The examination of genes involved in embryo development is the major use of zebrafish as a model system. The advantages are of course that (1) large numbers of embryos are fertilized *ex vivo* and develop outside of the mother, (2) the embryos are largely transparent, (3) transgenic approaches have been well established, and (4) mutational analysis as well as sequencing of the genome are well underway. All of these advantages also make this an excellent system with which the development of the circadian clock can be studied. Yet, having said this, there is considerable confusion about exactly when the clock starts and whether developing embryos need to experience a rhythmic environment or not in order to establish a functional clock. One report claims that the zebrafish embryos directly inherit a sense of time from their mothers. Certain clock genes appear to be maternally inherited in that mRNA encoding some of these clock genes is present in the zebrafish egg and early embryo prior to the onset of zygotic transcription. Experiments looking at clock gene oscillation (in particular, *zfper3*) claim that rhythmic expression of this gene begins almost immediately in development and when embryos are raised in constant darkness. This claim that the oscillation starts without exposure to a rhythmic light–dark environment (or supposedly any other entraining signals) forces the conclusion that these embryos must inherit the ''sense of time'' or phasing of this rhythm from their mother. However, studies from other groups draw the opposite conclusion. In order for melatonin rhythms or larval locomotor rhythms to be expressed, early embryos appear to require exposure to a light–dark cycle for at least two or more days. Embryos raised in constant darkness fail to show any rhythmic clock outputs. If the circadian clock is maternally inherited, then it does not appear to provide any functional clock outputs. Clearly, more studies are required to address and clarify this issue.

In comparison to the other model systems discussed in this issue and because of its recent arrival on the circadian scene, relatively little is still known about the circadian system in the zebrafish. However, homologs of most of the known clock genes have been identified in this system, and many aspects of the molecular machinery seem similar. We can expect an increase in knowledge and greater contribution from the fish when some of the genes mutated in ongoing clock screens have been identified. To date, perhaps the most interesting contribution of the zebrafish has been to help re-evaluate the role of central ''master'' clocks versus peripheral pacemakers in

a vertebrate system. The fish system was the first to reveal the presence of independent peripheral oscillators in a vertebrate, and the generation of multiple clock-containing cell lines may prove of real value in future biochemical studies.

3.4 Neurospora

Along with *Drosophila*, the fungus *Neurospora crassa* provided some of the earliest insight into how a molecular clock might be generated. Like *Drosophila*, this species has several significant advantages; powerful genetics, well-established molecular tools, and a robust and easy-to-measure circadian rhythm in the form of asexual spore production (conidiation). In nature, *Neurospora* grow as a syncytium of undifferentiated hyphae in which many nuclei are distributed throughout the cytoplasm. In the laboratory, cultures are grown in specialized hollow glass tubes called *race tubes* (~40-cm long and 16 mm in diameter). These tubes are turned up at each end, and along the entire length of the tube, a thin layer of agar medium provides the substrate for fungal growth. *Neurospora* spores are inoculated at one end of the tube and the fungus grows within the thin layer of agar along the tube. Under a light–dark cycle, every 24 h, a tuft of hyphae grow up and out of the agar (aerial hyphae) from which an orange, carotenoid-rich, conidium full of asexual spores develop. This rhythm in conidiation, noted early on by Pittendrigh, shows all the characteristics of a circadian generated behavior. Under constant darkness, the rhythm persists and freeruns with a period of approximately 22 h. The period of the rhythm is temperature compensated over a broad range of temperatures ($Q_{10} \sim 1$ between 18 and 30 °C), and the rhythm can be entrained by both light and temperature cycles.

In the Introduction, we argued that the circadian system can be divided into a conceptual framework of input, oscillator, and output elements. Although we stressed that this depiction is flawed (Fig. 3), it has provided the field (at least initially) with a useful way to both represent and search for the elements of the circadian system in all organisms. But as we shall see, the key clock genes of *Neurospora* (*frq*, *wc-1*, and *wc-2*) span multiple functions. As a result, the division of the *Neurospora* circadian system into input > oscillator > output works far less successfully than for the other species that we have considered in this review. But for the sake of consistency, we have followed the same general structure in this section, and forewarn the reader that the information is not easily contained within these headings. As a result, we suggest looking at the summary of the molecular clock of *Neurospora* in Fig. 6 before proceeding.

3.4.1 Entrainment

Until very recently, the photoreceptors entraining the circadian system of *Neurospora* remained largely uncharacterized, although two genes were implicated fairly early on. Mutant screens in *Neurospora* strains defective in light detection and phototransduction for a range of light responses, including phototropism, carotenoid biosynthesis, and circadian entrainment, would consistently identify two distinct genes: *white collar-1* (*wc-1*) and *white collar-2* (*wc-2*). In the context of the present discussion, the absence of *wc-1* or *wc-2* would completely abolish the light induction of the *frequency* (*frq*) gene of *Neurospora*, and as discussed below, the *frq* mRNA and FRQ protein are central to the

molecular clock in this species. The finding that light will induce rapidly *frq* provided one of the key insights in unraveling the clock mechanism.

In constant darkness, there is a circadian oscillation of *frq*/FRQ that peaks in the late morning and mid-afternoon respectively. After light exposure and induction of *frq*/FRQ, the phase of the clock corresponds to the *frq*/FRQ peak in the late morning/mid-afternoon. In constant light, *frq*/FRQ are constitutively elevated and arrhythmicity results. After the transfer from light to dark, levels of *frq* and FRQ decline rapidly, and FRQ becomes extensively phosphorylated and is degraded. The cloning of *wc-1* and *wc-2* indicated that WC-1 and WC-2 encode transcriptional activators that can bind via their GATA type zinc-finger DNA binding domains. The *frq* gene has two cis-acting GATA elements, called *light response elements* (LREs), which if mutated will either attenuate or abolish light induction of *frq* and entrained patterns of conidiation. Furthermore, electrophoretic mobility shift assays (EMSAs) were used to show that WC-1 and WC-2 are the trans-acting factors that interact with the *frq* LREs. WC-1 and WC-2 heterodimerize using their PAS domains and form the white-collar complex (WCC). Upon light exposure, this WCC has been shown to bind to these LREs and initiate transcription of *frq*.

An action spectrum of binding of the WCC to the LREs has implicated the involvement of a flavin-based photopigment, with a wavelength of maximum photosensitivity at ~465 nm. These *in vitro* studies showed a marked similarity to previously published *in vivo* results on clock responses to light, suggesting that the *in vitro* EMSA analysis was a real reflection of the circadian photosensitivity in *Neuorospora*. But what is the photopigment? Could it be WC-1 or WC-2 or even both? WC-1 contains a LOV (light, oxygen, voltage) domain, which has been shown in characterized photopigments to bind a flavin adenine dinucleotide (FAD) chromophore. Significantly, the LOV domain in WC-1 also binds FAD, and disruption of the LOV domain in WC-1 disrupts FAD binding and circadian photosensitivity.

The model emerging for photoentrainment of the *Neurospora* clock suggests that in the dark WC-1 and WC-2 form a WCC and bind the LREs on *frq* and this causes *frq*/FRQ production (remember, in the dark, there is a circadian oscillation of *frq*/FRQ). After light exposure, WC-1 (using FAD as the chromophore) acts as the blue light photopigment and undergoes a conformation change such that the WCC is then able to strongly activate the LREs on the *frq* promoter and activate *frq* transcription (Fig. 6). This light- dependent response can help explain the broad characteristics of a phase response curve to light (Fig. 2). For example, light will rapidly activate *frq* transcription at any time of the day. Thus, at dawn, when *frq* transcription is normally low, a pulse of light will drive *frq* to levels that would normally occur at mid-morning and hence advance the clock/molecular cycle. Conversely, a light pulse at dusk (when *frq* levels are normally falling under the dim-light conditions at the end of the day) will upregulate *frq* to levels encountered previously during the bright light conditions of daylight and hence delay the clock/molecular cycle.

Although WC-1 is an FAD-based photopigment, it is not alone in modulating the effects of light on the clock. A rhythmically expressed protein called *VIVID* (VVD), although not needed for clock function, appears to act as a negative regulator

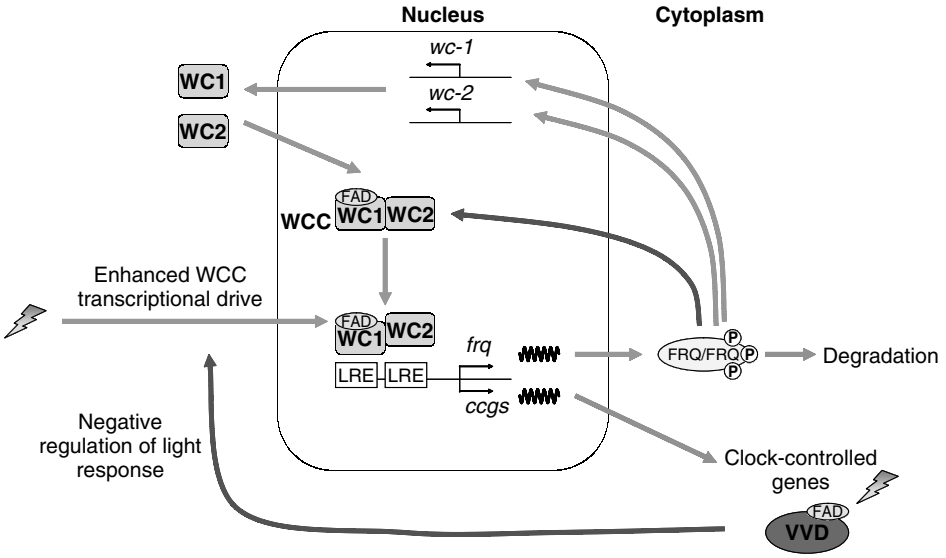

Fig. 6 The molecular clock of *Neurospora crassa* defies a simple compartmentalization into input > oscillator > output. The positive drive to the *Neurospora* clock is provided by *wc-1* and *wc-2* that form a white-collar complex (WCC) that enhances *frq* expression. The production of long and short forms of FRQ protein lead to the formation of homo- and heterodimers, which not only feed back to inhibit the WCC drive but also positively regulate the expression of *wc-1* and *wc-2*. FRQ stability determines period length. Light input is mediated through an FAD chromophore bound to WC-1 via an LOV domain. Light absorption results in a conformational change to the WCC, resulting in greatly enhanced *frq* expression. Clock-controlled genes also play a role in gating input signals to the clock. The protein VVD also contains an LOV domain and can bind the FAD chromophore in a similar manner to WC-1. VVD is rhythmically synthesized, and acts as a negative regulator of the light-induced WCC transcriptional drive.

of light responses. For example, *frq* transcription is more sensitive to light in *vvd* mutants. How VVD acts remains unclear but probably via an interaction with the WCC. VVD, like WC-1, has a LOV domain and binds FAD and is thought to be a blue light photopigment. VVD itself is light regulated, with levels low in the dark and high in the light. In addition, *vvd* expression requires the WCC. Thus, VVD not only acts as a negative regulator of the WCC in the light but also requires the presence of the WCC and light for its own expression (Fig. 6). The rhythmic expression of *vvd* presumably comes about as a result of the negative feedback of FRQ on the WCC (see below). As such, VVD provides an example of a clock-controlled gene that is also capable of regulating the input to the core oscillator. As VVD is influenced by an output from the clock, and VVD acts on the input pathway, it can be called a *zeitnehmer*.

3.4.2 Oscillator

Early in the field of molecular chronobiology, the *frq* gene was identified as a critical component of the clock. Mutations in *frq* would shorten, lengthen, or abolish free-running rhythms of conidiation. Significantly, these mutations appeared to cause no obvious morphological or

physiological defects, suggesting that *frq* acted specifically within the *Neurospora* clock. A chromosomal walk finally cloned the gene and the functional analysis of *frq*/FRQ began. It was shown that *frq* mRNA and FRQ protein levels cycle with a 22-h period in free-running wild-type strains and that the period of these oscillations matched the period of conidiation found in long and short mutant strains. A fusion gene, consisting of the *frq*-coding region attached to an inducible promoter, showed that the constitutive expression of *frq* would abolish circadian rhythms of conidiation. In addition, by driving levels of *frq* from high to low (removing the inducible agent) at any time of the day would reset the clock to dusk, which corresponds to the low point of *frq* mRNA in wild-type strains (*frq* levels reach their peak some 4–5 h after dusk). A negative feedback by FRQ on *frq* transcription was supported by the finding that defective FRQ protein would result in constant high levels of *frq*. Indeed, more recently, nuclear localization has shown to be critical for both behavioral and molecular oscillations in *Neurospora*. Thus, it was established fairly early on that *frq*/FRQ appears to be part of a molecular feedback loop that is essential for the generation of circadian rhythmicity. But, of course, *frq* is not the only gene involved in the fungal clock.

As discussed above, the WCC acts in the dark as the positive element of the *frq*/FRQ negative feedback loop and is part of the entrainment pathway under a light–dark cycle. Two forms of FRQ (long or short) are transcribed and associate as either homodimers or heterodimers to form a protein complex. When the FRQ complex reaches a certain level, it enters the nucleus and inhibits activation of *frq* transcription by interfering with WCC-driven transcription, and hence closes the negative feedback loop. Phosphorylation of FRQ occurs immediately after translation and targets FRQ for eventual degradation. Several kinases have been implicated in this process including casein kinase I, casein kinase II, and a calcium-/calmodulin-dependent kinase. The stability of FRQ in turn determines the period length of the oscillation. FRQ has also been shown to positively regulate expression of both WC-1 and WC-2, probably via different mechanisms (Fig. 6).

Thus, *Neurospora*, like other molecular clocks we have encountered, has both positive and negative transcriptional drives for the generation of the circadian oscillator. Although FRQ is an essential clock element, suggestions that *frq* was not the sole oscillatory component of the circadian system in *Neurospora* go back to 1986. Returning to this observation, and using *frq* null mutants, Merrow and colleagues employed traditional circadian entrainment protocols (''T-cycles'') in an attempt to clarify the role of *frq* within the circadian system. They found strong evidence for a temperature, but not light, entrainable oscillator in *Neurospora*. The nature of this or these addition feedback loops remain uncharacterized, and their identification forms an ongoing focus for the *Neurospora* research community.

Neurospora has also provided insights into the underlying mechanisms of temperature compensation. Temperature effects in *Neurospora* appear to be mediated through the amount and type of FRQ protein made, with FRQ oscillating around higher levels at higher temperatures. As noted above, two forms of FRQ protein are produced, and temperature also appears to regulate the relative levels of these long and short forms by favoring differing initiation codons at different temperatures. When either of these initiation codons is

removed, the range of temperatures over which the clock will function is reduced.

3.4.3 Output

As discussed above, *vvd* is one example of a clock-controlled gene, but a large number of additional genes are emerging that are under clock regulation. These genes are associated with every aspect of *Neurospora's* biology, ranging across reproduction, development, behavior, and metabolism. One of the most intensely studied has been glyceraldehydes-3-phosphate dehydrogenase (GAPDH). GADPH acts as a catalyst in the first step of glycolysis. It is a critical enzyme in the glycolytic cycle and couples the oxidation of the glyceraldehydes-3-phosphate substrate to its phosphorylation. The oscillation in GADPH and other critical housekeeping genes is substantial, but a robust oscillation does not necessarily mean that the gene is a clock-controlled gene. The point that has often been made is that it is difficult to address whether rhythmic genes are regulated by the clock directly or merely as a by-product of rhythmic changes in the cellular environment. As with the other genetic models, microarray analysis is being used to assess the global pattern of rhythmically expressed genes in *Neurospora*, and like *Drosophila*, mice, and *Arabidopsis*, approximately 2–6% of the genome appears to be under some form of clock regulation.

3.5 Arabidopsis

The common theme in this manuscript has been to describe the major impact that forward genetics, and the identification of the particular mutated genes, has had on progress in understanding the biological clock in a wide range of species. It should be of no surprise then that in plants the primary model system is one renowned for its genetic accessibility, *Arabidopsis*. Our understanding of plant clocks is mainly due to progress in this species (Fig. 7).

3.5.1 Entrainment

To plants, of course, light is more than simply a signal of dawn and dusk, but critically the source of their ''energy'' through photosynthesis, and a regulator of their reproduction through flowering, on an annual or photoperiodic basis. As such, plants have evolved a large number of photopigments with which they take maximum advantage of the light source to which they are exposed. It is not surprising, therefore, that a large number of photopigments have been implicated in the regulation of the circadian clock.

The classic manner of examining the light characteristics of the circadian system is to provide a series of short, discreet light pulses of varying wavelengths and intensities and then determine the change in some clock parameter (circadian phase, acute gene induction, etc.), or in other words, to generate an action spectrum. This short term or acute action of light on clock phase can be seen as being equivalent to nonparametric entrainment, that is, the ability of short light pulses to mimic the action of long, sustained light effects (parametric entrainment). Phase shifting and the generation of action spectra to short light pulses have not yet been performed in *Arabidopsis*. However, extensive data has been produced regarding the effects of sustained, constant light treatments of specific wavelengths and intensities (fluence rate). This is made possible by the fact that the *Arabidopsis* circadian clock continues to run under constant light treatments and shows very reproducible changes in period length, depending upon the wavelength and intensity of light. In

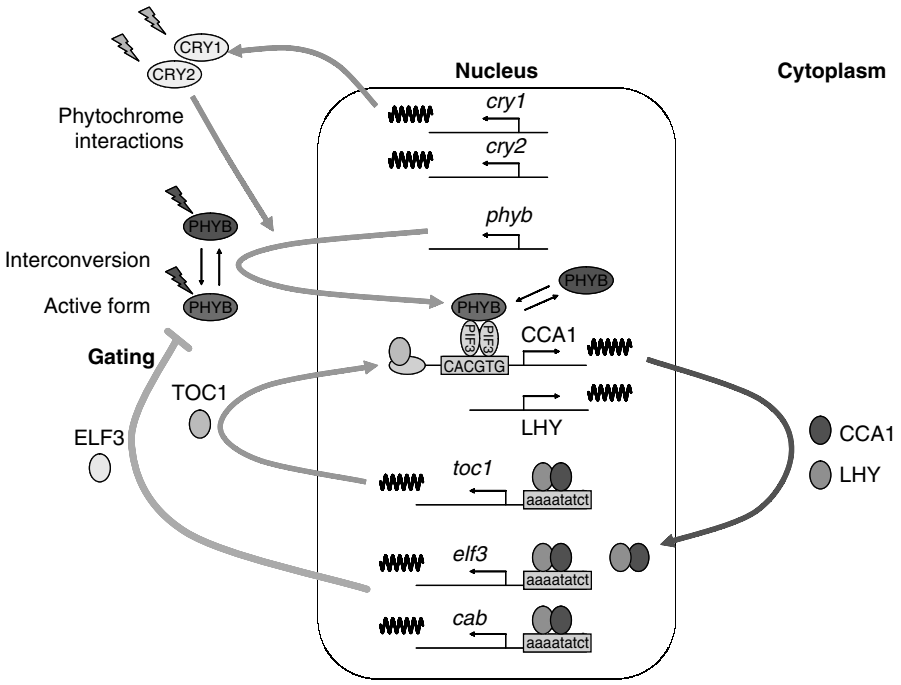

Fig. 7 Model of the molecular clock of *Arabidopsis thaliana*. Entrainment of the *Arabidopsis* circadian clock is thought to occur through a combination of the actions of cryptochromes and phytochromes. Cryptochromes function primarily in the blue region of the spectrum, with phytochromes acting in the red–far red region of the spectrum. Phytochrome undergoes nuclear entry following absorption of an activating photon of red light (converting it to the active far-red absorbing form). In the nucleus, phytochrome interacts with the bHLH transcription factor PIF3. This complex then increases the transcription of downstream genes containing the PIF3 DNA binding site, a G-box (CACGTG). The circadian-regulated output protein, ELF3 is thought to feed back on to the clock input pathway, and, as a consequence, gate the clock response to light to particular times of day. Two rhythmic gene products are essential components of the negative limb of the circadian oscillator. Transcripts for the genes *lhy* and *cca1* peak around the late subjective night/early dawn. Transcript levels for the gene *toc1* show oscillations 12 h antiphase to this, peaking at the end of the late subjective day. LHY and CCA1 proteins are capable of binding directly to a DNA motif in the promoter of the *toc1* gene. This DNA binding motif, termed an *evening element* (AAAATATCT), is not only found in the promoter of *toc1* but also in a number of clock output genes. TOC1 is thought to be the positive element of the circadian oscillator, acting to increase the transcriptional rates of *cca1* and *lhy*. These three proteins compose the central, core elements of the *Arabidopsis* circadian clock.

fact, the application of constant red and blue light caused a shortening of the circadian period, as measured in a transgenic *Arabidopsis*, which contained the luminescent reporter gene luciferase linked to the rhythmic promoter of the chlorophyll a/b binding protein gene (*cab::luc*). Further studies, taking advantage of specific mutant seedlings with null mutations in identified photoreceptive molecules, has allowed the roles of these particular photopigments to be determined even further. The results show a wide and complex arrangement of photosensory systems in the

plant, which allow for clock entrainment in response to many wavelengths of light (see below).

Arabidopsis contain five types of phytochrome, from PHYA to PHYE, which, generally speaking, absorb light in the red and far-red region of the spectrum. They are quite similar molecules of about 124 kDa and possess a covalently linked chromophore molecule consisting of a linear tetrapyrrole. Phytochromes exist within the cell in two states that can be interconverted from one to the other, depending upon the wavelengths of light they absorb. Upon initial synthesis, phytochrome is in an inactive red absorbing form (Pr), but upon absorption of a photon of light converts to the active far-red absorbing form (Pfr), in which it can regulate a wide range of physiological responses. This number of phytochromes provides the cell with a range of detection sensitivities. For example, PHYA is thought to function primarily in response to low-level red light, while the other phytochromes function under more intense red light conditions. *Arabidopsis* also contains two members of the cryptochrome family of proteins (CRY1 and CRY2). These photopigments absorb light in the blue/UV region of the spectrum using two chromophores, a light-harvesting pterin and a catalytic flavin.

Somers and colleagues crossed the transgenic *cab::luc* reporter plants to individuals with null mutation in two of the phytochromes, *phyA* and *phyB*, as well as to mutants for both *cry1* and *cry2*. The resulting mutant reporter seedlings were then tested under constant light conditions of varying wavelengths and intensities. The *phyA* mutant seedlings showed a loss of response to low intensities (low fluence rates) of both red and blue light. By contrast, the *phyB* mutants lack normal responses to high intensities of red light. The presence of these two pigments clearly provides the plant with a detection system that works optimally at differing intensities of light. A double mutant lacking both *phyA* and *phyB* showed that these two photopigment systems normally work additively. The *cry1* mutant seedlings lack a wild-type response to both high and low fluence levels of blue light, but respond normally to intermediate intensity levels. *cry2* mutants showed little alteration in the light response, but most likely act in a redundant manner with *cry1* at intermediate fluency levels. CRY1 is apparently the primary blue light–responsive photopigment at high light intensities, with CRY2 undergoing light-dependent degradation.

Interestingly, PHYA and CRY1 have been shown to interact physically at the protein level in yeast. At low light intensities, it is now believed that CRY1 acts downstream of PHYA, as a component of the signal-transduction cascade for PHYA light detection in the red wavelengths. This is not the only interaction that occurs between phytochromes and cryptochromes, as PHYB has been shown to interact with CRY2 by immunoprecipitation. This complex appears to form ''nuclear speckles'' in a light-dependent manner, but the exact functional meaning of this is not yet clear. This light-dependent nuclear localization is a critical event for light regulation of downstream gene expression (see below). In both tobacco and *Arabidopsis*, GFP protein fusions with PHYB show light-dependent nuclear entry. A nuclear localization signal exists in the carboxy terminus of this protein in *Arabidopsis*, and red light exposure promoted cytoplasmic to nuclear translocation. In tobacco, both PHYA and B undergo such light-driven movement, though PHYB translocation is inhibited by far-red light in contrast

to PHYA. The remaining phytochromes, PHYD and E, all appear to act in a redundant manner with PHYB to detect light of higher irradiances in the red region of the spectrum. Several triple mutants, including *phyA*, *phyB*, and *phyE*, showed a reduced response at high intensities of red light. However, all triple mutants examined so far still showed responses at low intensities of red light, possibly arguing for an additional, but as yet unidentified, role for *phyC*. Nevertheless, consensus implies that PHYB is certainly a predominant photopigment in red light detection for many aspects of light-regulated physiology in *Arabidopsis*.

Several additional regulators of light responsiveness in *Arabidopsis* have recently been identified, again through use of mutant seedlings. Mutations in the gene *sensitivity to red light reduced* (*srr1*) showed a reduced sensitivity to red light, as the name would suggest. A range of phenotypes in this mutant showed great similarity to defects seen in *phyB* mutations, suggesting a strong link between the roles played by both molecules. The acute induction of *cab* gene expression, which normally occurs in response to red light pulses, is in fact, increased in *srr1* mutants. The actual mRNA levels of *srr1* are themselves increased in response to red light, but not far-red light, pulses in an acute manner, with levels raised within 2 h of the pulse. However, transcript levels do not appear to oscillate across the circadian cycle when plants are monitored in constant light. This might suggest that the *srr1* is not involved in the central clock mechanism itself, but by measuring the period of the clock with *ccr2::luc* transgenic reporter lines in *srr1* mutants, it was apparent that there was a shortening of some 1.6 h in mutant versus wild-type plants. *srr1* clearly has a role not only within the light-detection machinery but also the clock mechanism itself. One interesting aspect of *srr1* is the fact that homologous genes appear to be present in a wide range of species, including mammals and flies. It will be interesting to see if this gene plays a role in clock function or light-entrainment pathways in these species as well as *Arabidopsis*.

As mentioned above, a critical aspect of phytochrome B red light signaling appears to be its light-dependent nuclear translocation. PHYB has been shown to directly bind to a bHLH factor known as *PIF3*, but only after conversion to its active far-red form (PfrB). PIF3 is a nuclear protein and binds to a DNA regulatory motif known as a *G-box*. It is of considerable interest that a G-box recognition sequence, CACGTG, is of course identical to the ''classical'' E-box sequence believed to be critical for circadian clock gene regulation in *Drosophila*, mammals, and zebrafish. The binding of photoactivated PHYB to PIF3 is thought to activate PIF3, and so turn on the transcription of genes containing this G/E-box motif. It is through this nuclear translocation of activated PHYB, binding to PIF3 and then activation of genes containing G-box recognition sites, that red light exposure can regulate downstream gene activation.

A defining feature of circadian clocks is their required ability to entrain to light–dark cycles and the additional fact that identical light pulses can either phase advance, phase delay, or have no effect on the phase of the clock, depending upon the time of day that they are given (Fig. 2). The nature or shape of this phase response curve (PRC) is critical for stable entrainment of the clock. There are also a number of examples where a given light pulse can acutely induce the transcription of a given gene at one time of day but not another.

As discussed in Sect. 3.4.1, the action of light on the clock can be gated by the clock itself, such that a clock output can feed back to regulate the light input pathway. Such an event has been termed a *zeitnehmer*. An example of a gene thought to be involved in such a process is *elf3* in *Arabidopsis*. The *elf3–1* (*early flowering3–1*) mutation was first discovered in a mutant screen for altered flowering phenotypes, but possessed several distinct circadian phenotypes also. Rhythms in the gene *cold circadian regulated 2* (*ccr2*), as measured by bioluminescence of a *ccr2::luc* transgenic plant, become arrhythmic in *elf3* mutant plants grown in constant light, but continue to oscillate in constant darkness, without a change in clock period. *elf3* cannot be a central component of the clock therefore, as the pacemaker continues to run normally in the mutant background. However, *elf3::luc* plants show that *elf3* itself oscillates in constant darkness, and so must be an output of the clock under rhythmic transcriptional control. Additional studies using *elf3* overexpression showed that the period length of the clock lengthened under constant white light conditions but remained unaltered in constant darkness. The ELF3 protein must, therefore, be feeding back to regulate the circadian clock response to light. This was confirmed by examining the shape and amplitude of the phase response curve to short, 1-h pulses of either red or blue light. The *ccr2::luc* transgenic plant made an examination of nonparametric entrainment, entrainment to short light pulses, possible for the first time in *Arabidopsis* due to its sustained rhythmicity under constant dark conditions. Overexpression, as well as the null mutation in *elf3*, caused distinct changes in the PRC amplitude. Overexpression of *elf3* caused a loss in the ''sharpness'' of the breakpoint at which light pulses change from causing delays to when they cause advances. Furthermore, overexpression tended to reduce the size of phase shifts, especially in red light, whereas the null mutation tended to increase the size of shifts or lead to arrhythmia. The conclusion to these data is that *elf3* is a clock output that is capable of feeding back to regulate the pacemakers response to light pulses or constant light conditions in a negative manner.

3.5.2 Oscillator

Mutations in the plant cryptochromes and phytochromes do not abolish circadian function, and so these light-detecting molecules themselves do not appear to be the central components of the clock. Clearly, this distinguishes the role of the cryptochromes in plants from the central clock role in, for example, mammals. Though there are still many gaps in our understanding of how the *Arabidopsis* clock functions, again much has been learned from the analysis of specific mutants.

A mutation in the gene *late elongated hypocotyl* (*lhy*) generated a number of aberrant circadian phenotypes, including a strong tendency for loss of rhythmicity in leaf movements, as well as the rhythmic circadian regulation of some gene expression, including that for both *cab* and *ccr2* genes. Furthermore, this mutation caused flowering to occur independently of the photoperiod upon which the plants were grown. The *lhy* gene encodes a MYB-DNA binding protein, and mRNA levels show a circadian oscillation with peak expression around dawn. This oscillation is lost in the mutant, while overexpression of the gene in a transgenic leads to a reduction in endogenous transcript levels. Further analysis of additional *lhy* mutant alleles showed a distinct period shortening in the oscillation of certain genes, such as

the gene *circadian clock associated* (*cca1*) by about 2–3 h (see below). These data together strongly suggest that LHY can feed back negatively to suppress its own transcription, a key and common characteristic of many central clock components, but that it may not function alone in this role (Fig. 7).

A similar MYB-like DNA binding protein, circadian clock associated (CCA1), shows a similar oscillatory profile, with both mRNA and protein oscillating. Overexpression of CCA1 also leads to a repression of endogenous transcript levels, again arguing for its role as a component of a negative feedback loop. Mutations in the *cca1* gene show a shortened period compared to wild types. However, these oscillations do continue to run with this altered period for several days, and so, as with LHY, CCA1 cannot be acting alone as a negative transcription regulator. Data from double mutants, lacking both LHY and CCA1 proteins, would be essential to determine if these two molecules were acting in a redundant manner. Existing data suggests this, as double mutant plants show rapid dampening of circadian rhythms in constant light and dark conditions. CCA1 and LHY appear to be partially redundant, but are essential proteins if the clock is able to continue running in a sustained manner. They are critical players in the negative limb of the circadian clock mechanism in *Arabidopsis*, but it would not be surprising if more components were yet to be discovered.

If CCA1 and LHY are critical negative regulators of the plant clock, what are the positive clock regulators? In 1995, a number of *Arabidopsis* short- and long-period mutants were identified in a screen using *cab::luc* luminescent transgenic plants. One mutant, called *timing of cab expression* (*toc1*), was a semi-dominant mutation, leading to a shortening of both the *cab* gene expression rhythm and the normal oscillation in primary leaf movement. Five years later, the *toc1* gene was cloned and was shown to encode a protein containing several previously identified domains; an atypical response regulator receiver domain, found in some bacterial two-component signal transduction systems, and an acidic domain as well as a region found in several CONSTANS family transcription factors. TOC1 was likely to play a critical role as a transcription factor, and the fact that its mRNA levels oscillated with a peak at the end of the subjective day supported its role as a central clock component.

The fact that *cca1* and *lhy* transcripts oscillate 12 h out of phase with TOC1 transcript levels strongly suggests that a form of oscillatory feedback loop is likely to exist between these genes. Further analysis of *toc1* mRNA in plants overexpressing CCA1 or LHY showed that TOC1 transcript levels ceased to oscillate and declined to below levels seen at the trough point in matching wild-type strains. CCA1 and LHY are, therefore, likely to act negatively on the transcription rate of TOC1. This was confirmed by an analysis of the *toc1* promoter, where binding of CCA1 and LHY directly to regulatory elements was shown to occur. This element, known as the *evening element* (*EE*) was found to be common to a number of genes that showed peak expression in the late subjective day. Two mutant alleles of *toc1* have been identified. The *toc1-1* allelic form was the first mutant identified, and is a semi-dominant mutation, which retains some TOC1 function. *toc1-2* is a recessive mutation, and most likely represents a loss of function of TOC1. An examination of *cca1* and *lhy* mRNA levels in *toc1-2* mutants revealed a dramatic decrease in the peak amplitude of both

rhythms. It has been proposed, therefore, that TOC1 represents a component of the positive limb of the circadian clock mechanism, acting as a positive transcriptional regulator of both *cca1* and *lhy* expression. However, the fact that both *cca1* and *lhy* both continue to oscillate in the *toc1-2* null mutant must mean that other components that perform this role also exist. A schematic of how these molecules may fit together can be seen in Fig. 7.

3.5.3 Output

Perhaps, the ''oldest'' of all circadian outputs, or at least the first described, can be attributed to higher plants, with the description of leaf movements in constant darkness by de Mairan in 1727. This assay is still used regularly today in mutant screens of *Arabidopsis* seedlings. A wide range of plant physiological processes are under clock control, including stomatal opening, CO_2 assimilation, and the timing of flower opening in some species. Plants that grow in desert environments are under very strong selective pressure-to-time aspects of their physiology to certain times of day, as is true of course for desert-dwelling animals as well. Crassulacean acid metabolism, found in what are generally termed *CAM* plants, is a particular adaptation to such environments and enables such plants to fix CO_2 during the night while keeping stomata closed during the day. The temporal regulation of such stomatal closure is obviously critical if water loss is to be minimized. However, the exact balance of clock regulation, versus that of acute environmental cues, on CAM function is not yet completely clear, especially as this type of metabolism cannot continue under constant light conditions.

An analysis of clock-regulated gene expression, using microarray technology or ''DNA chips,'' has been performed in *Arabidopsis* by several groups. Estimates of between 2 and 6% of all genes are believed to be under clock control, though the final number is likely to be much higher. Perhaps, not surprisingly, genes involved in the light-harvesting reactions of photosynthesis showed strong circadian regulation, as did the genes involved in starch mobilization, nitrogen metabolism, and many other such processes. The study of Harmer and colleagues revealed the presence of the ''evening element'' within the upstream promoter regions of some 31 cycling genes that showed peak expression in the late subjective day. This ''evening element'' is composed of a remarkably conserved 9-nucleotide motif, AAAATATCT, which appears to be important for clock regulation of these rhythmic genes. This global clock regulation of gene expression bears remarkable similarity in scale, if not detail, to that seen in a number of mammalian tissues and shows how central the circadian clock is to the physiology of most organisms.

Of course, one of the most remarkable seasonal responses of many plant species is the annual regulation of flowering and reproduction. Such processes are regulated by measurement of day length as a photoperiodic response. Though this topic is beyond the scope of this review, it is interesting to note that several clock genes have been implicated in the regulation of flowering in *Arabidopsis*. This is particularly true for the *toc1-1* mutant discussed above. *toc1-1* plants are unresponsive to photoperiod when grown on light–dark cycles of 24 h (a normal day length). However, when grown on cycles of 21 h, which matches the natural free-running period of this mutant, individuals can distinguish between short and long days. In addition, overexpression of the

circadian negative regulators CCA1 and LHY will delay flowering on long days. While the *elf3* mutant also influences the time of flowering, two additional mutants that alter flowering time are of particular interest. Both ZEITLUPE (ZTL) and FKF1 represent a similar class of molecule that contains a LOV domain, a subgroup of PAS domain proteins, as well as F-box motifs. F-boxes have been strongly implicated in targeting proteins for degradation via the ubiquitin pathway and LOV domains have been implicated in events relating to blue light photoreception. Mutations in both of these genes have a robust effect on *Arabidopsis* flowering events. Mutations in *ztl* also lengthen the free-running period of genes under clock control. So, it is clear, as one would expect, that there is a strong and intimate link between genes involved in the generation and regulation of the daily or circadian clock and the expression of annual rhythms, such as flowering.

3.6 Cyanobacteria

The cyanobacteria are the first prokaryotes that have been shown to possess a circadian pacemaker. This was an important step forward in expanding our understanding of the evolution of clocks and an added example of how incredibly widespread the phenomena of circadian oscillations really are. It was long assumed that prokaryotes, with their generally very fast (shorter than 24 h) cell cycles, would not possess or have a need for a clock, but this is clearly not true. Nor is the presence of a nucleus (a new form of biological snobbery) required either.

With the recent sequencing of many bacterial genomes, it has become apparent that the presence of one central cyanobacterial clock gene, *kaiC*, is more widespread than simply within the cyanobacteria, being found also in the Archaea and Proteobacteria (though only the cyanobacteria contain the complete family of the *kai* genes; see below). This is of course not proof that clocks are widely distributed amongst many bacteria but certainly demonstrates the very early evolution of genes that are involved in the clock mechanism. The first *kai* genes may have appeared some 3500–3800 million years ago, before the presence of an oxygen atmosphere on the earth. Cyanobacteria, of course, tend to be photosynthetic, and as such the potential value of a circadian clock is clear. It is not yet known how widespread functional clocks may be amongst prokaryotes. However, as many human disease states are caused by bacterial infection and other prokaryotic organisms, the presence of a clock and the timing of certain physiological processes to a particular time of day may prove to be a very valuable clinical tool and have considerable medical implications.

As we shall see, most of the molecules of the cyanobacteria, and how they may work, appear quite alien (and unique) to individuals more used to mammalian transcriptional regulation. However, many of the basic aspects of how one generates an oscillation are similar, including the critical importance of negative feedback with delay. The cyanobacteria provide a fascinating and unique view of alternative ways of generating a circadian oscillation.

3.6.1 Entrainment

Relatively little is currently known about light detection and the details of the input pathway to the clock in cyanobacteria. Changes in the lighting regime (timing

of the LD cycle) are capable of reentraining the clock in *Synechococcus* RF-1, but few, if any, typical short light pulse, phase shifting experiments have been performed in this species. However, recently, Golden and colleagues did isolate a mutant (*Synechococcus* sp. PCC7942) that showed an impaired ability to phase shift in response to 5-h dark treatments. The gene underlying this mutation was isolated and called *circadian input kinase* (*cikA*). *cikA* encodes for a bacterial phytochrome, containing histidine kinase motifs, which raised the possibility that this molecule might be acting as a putative bacterial photopigment. The importance of phytochromes in the circadian system of higher plants added support to this idea. However, sequence comparison shows that *cikA* lacks a critical amino acid residue thought to be essential for binding of a required chromophore. In addition, the optimal wavelengths for phase shifting the clock appear to be in both the blue and red regions of the spectrum, with green and far red having little or no effect. This spectral response is not quite what one might predict for a typical phytochrome response nor is it similar to that one would expect for a photosynthetic response. At present, the photopigment responsible for *Synechococcus* entrainment remains unknown, and further data will be required to confirm the exact role of *cikA* in the clock input pathway.

Within the last year, a new class of cryptochrome flavoproteins (called *cryptochrome DASH*) has been isolated in the related cyanobacteria, *Synechocystis*. This gene has considerable sequence homology to photolyases but has the capacity to act as a transcriptional repressor. Whether this bacterial cryptochrome will have a central clock role or potential photoreceptive role as in other circadian systems still remains to be tested. However, the presence of cryptochrome in cyanobacteria is interesting, if not least for the fact that it reveals how early this class of molecule appeared on an evolutionary timescale.

It is perhaps important, especially when dealing with an unusual system like cyanobacteria, to keep an open-mind about the possible mechanisms of light detection and not get locked in a very mammalian, classical signal transduction perspective. Light, for example, has profound effects on the RNA stability of a number of cyanobacterial transcripts. These include transcripts like *psbA2*, a molecule centrally involved in the function of photosystem II in the photosynthetic machinery and believed to be a rhythmic output of the circadian clock. A short stretch of the 5′-untranslated region (5′UTR) of this transcript contains an ''AU-box'' (UAAAUAAA), which, when deleted, removes light-dependent regulation of *psbA2* expression. This region of RNA appears to increase transcript instability in the dark and may aid accumulation in the light via putative positive and negative cis-acting factors. Light is acting in a posttranscriptional manner to influence transcript levels and presumably subsequent protein levels. At this time, no evidence for such a mechanism in the circadian input pathway, or in stabilizing central clock transcripts, has been demonstrated.

3.6.2 Oscillatorff

Identification of central clock genes in cyanobacteria has progressed through the use of mutant screens/forward genetics, as in most other circadian model systems. The prerequisite for such screening is the availability of a reliable wild-type phenotype against which to compare potential mutants. Though there are a number of rhythmic outputs in cyanobacteria, including nitrogen fixation, photosynthetic

activity, and cell cycle regulation, these are not necessarily the easiest of assays to use with which to identify mutant strains. One major advantage of bacteria, of course, is the relative ease with which one can introduce genes and stably integrate them in the genome via homologous recombination. The generation of a luminescent reporter strain, with luciferase under the control of a clock gene promoter, would provide a very clean and relatively easy assay for circadian rhythmicity and the subsequent isolation of mutants. To be more exact, the upstream promoter region of the gene *psbA1* (another molecule involved in the function of photosystem II) was fused to luciferase (*luxAB*) and the luminescent reporter strain AMC149 of *Synechococcus* sp. PCC7942 was generated. This strain showed robust circadian oscillations, showing that the promoter of *psbA1* was under clock control.

Interestingly, the random insertion of a luciferase reporter, in a ''promoter trap'' style experiment, revealed something quite unexpected. Of approximately 3000 randomly transformed colonies, 800 were sufficiently bright to allow for imaging by use of a cooled CCD camera system. When examined for circadian cycling, almost all of these 800 transformants showed circadian oscillations in bioluminescence with a range of amplitudes and waveforms. Some 80% of these colonies had the same phase relationship to the light–dark cycle as *psbA1*. The majority, if not all, of the genes in *Synechococcus* are under global clock control. The default state for gene transcription in this system is to oscillate, and so it appears that there must be some non-gene-specific regulation of the transcriptional machinery. This idea was extended by the fact that even heterologous promoters, in particular the promoter of *conII* from *Escherichia coli*, show robust circadian oscillations when inserted into cyanobacteria.

Additional evidence that supports the idea of a global circadian regulation of transcriptional state includes the fact that when the recently identified clock genes (*kaiBC*) in cyanobacteria were placed under the control of a heterologous promoter, the transcripts from these genes continued to oscillate. In other words, the exact nature of the promoter, in terms of sequence specifics, did not seem to matter in terms of regulating rhythmicity, and so the regulation must be at a more general level. Furthermore, one of the new clock genes, *kaiC*, bore considerable resemblances to bacterial recombinases and helicases, that is, molecules involved in the general winding and unwinding of chromosomal DNA. Though this was not a proof of a novel transcriptional mechanism, this certainly supported the idea of a global regulation of transcription by changing the supercoiled state of the bacterial chromosomal DNA. Johnson and colleagues have proposed a model, therefore, where this global rhythm in the transcription of apparently all cyanobacterial genes is controlled by large-scale changes in the state of the bacterial chromosome, with regulation occurring as a change in the supercoiled nature of the DNA. The state of the whole ''nucleiod'' changing rhythmically and so being termed (somewhat disagreeably) the *oscilloid*. Similar changes in gross DNA state have been reported in the chromosomal DNA of chloroplasts found in *Chlamydomonas*, and as chloroplasts are thought to have originated from the inclusion of endosymbiotic cyanobacteria, this also tends to support the rhythmic supercoiling regulation of DNA as a means of achieving rhythmic gene transcription.

The generation of a luminescent reporter strain of cyanobacteria allowed for a

large scale, semiautomated mutant screen to be performed. Approximately 500 000 individual clones were mutagenized by EMS, and then screened for period length defects or other circadian phenotypes. A large number of mutants were isolated, of which 12 displayed altered period ranging from 16 to 60 h and a number of others showed complete arrhythmia. The exact genes mutated in such a screen could be identified by rescuing the given mutants through complementation with libraries constructed from wild-type *Synechococcus* DNA, with more than 30 mutants rescued so far in this manner. This rapid and compelling method of identifying mutant genes is a far cry from the laborious gene mapping approaches required in vertebrates, and allowed for the efficient isolation of the critical genes involved in rhythm generation.

The majority of these mutations revealed three critical clock genes in *Synechococcus*, called *kaiA*, *kaiB*, and *kaiC*, which exist in a tight gene cluster referred to simply as *kai* (kai meaning *rotation* or *cycle* in Japanese). Nineteen of the mapped mutations can be localized to these three genes. The *kai* genes appear to be unique clock molecules in that, based on sequence comparison, they bear no resemblance to clock genes identified in other species (and as such may represent the independent evolution of a circadian clock). All three genes appear to be critical for normal clock function, with *kaiB* and *kaiC* being cotranscribed and thus forming a bacterial operon. Whereas *kaiA* transcription appears to be under independent regulation, *kaiC* is the largest of the three genes and as such is the site of most mutations affecting period length. Sequence comparison places kaiC as a potential member of the RecA/DnaB family of proteins, suggesting, as mentioned above, a potential role in the regulation of DNA structure. RecA proteins act as ATP-dependent DNA recombinases and DnaB proteins function as replication fork helicases. kaiC is able to bind ATP through the presence of two Walker A motifs (regions involved in ATP binding). Mutation of these Walker A regions disrupts ATP binding and has a seriously disruptive effect on the generation of circadian oscillations. This ATP binding event appears to be essential for the function of kaiC proteins, as in the presence of ATP kaiC associates to form homohexamers, which are visible as rings with a central pore when examined under an electron microscope. As such, kaiC appears to be able to bind directly to forked DNA, again supporting the idea of a role in regulating the global status of DNA supercoiling in *Synechococcus*.

All three genes show a peak in expression at around CT 8, when maintained in continuous light, with the peak in kaiB and kaiC protein expression occurring some 8 h later at CT 16. Such large delays between peak transcript levels and protein levels have been seen in systems such as *Drosophila*, and may be an essential requirement for the generation of long, 24-h periods, as seen in the circadian clock. Such a large lag requires considerable posttranscriptional regulation of the nascent RNA, with presumably mechanisms in place to delay translational activation, as well as processes involved in regulating RNA stability. The delays supposedly produced by controlled nuclear entry clearly cannot occur in a system lacking a nucleus.

The three *kai* genes form an interactive feedback loop responsible for the generation of the circadian rhythm (Fig. 8). All three proteins appear to be able to interact with each other when tested in a yeast protein interaction assay. If kaiC is

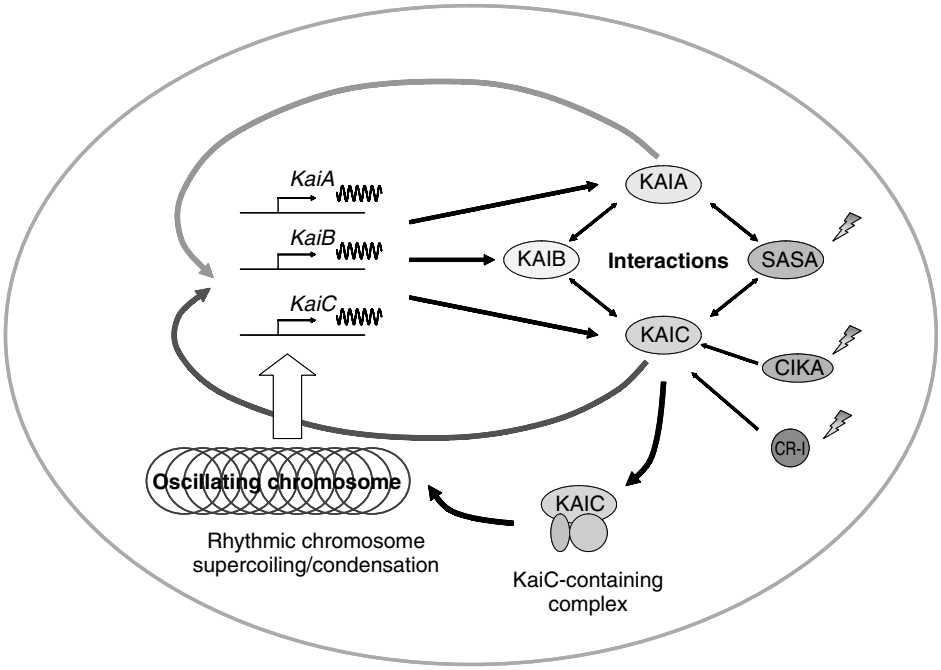

Fig. 8 Model of the molecular clock of Cyanobacteria. The central clock mechanism in cyanobacteria appears to be based on the Kai gene complex and proteins (*kaiA, kaiB,* and *kaiC*), as well as the potential rhythmic coiling and uncoiling of the bacterial chromosome. This global change in chromatin structure may underlie the circadian rhythmicity seen in all genes studied to date. *kaiB* and *kaiC* are cotranscribed as part of a bacterial operon, but all three genes are rhythmic with a peak in expression in the mid-subjective day. Protein levels peak some 8 h later, around CT16 in the subjective night, showing the typical transcription–translation delay seen in many circadian systems. KAIC appears to be capable of binding forked DNA, and as such may play a role in regulating the global genes seen in chromatin structure. The three Kai proteins can interact to form a Kai protein complex, possibly including the protein SASA. KAIC feeds back negatively to repress transcription of itself and *kaiB*, thus representing the core negative feedback element of the clock. KAIA appears to act positively on the transcription of *kaiB* and *kaiC*, along with SASA, and so these proteins represent the positive limb of the circadian clock mechanism. Entrainment of this core oscillator may occur through the action of the bacterial phytochrome *cikA*, but further data will be required to confirm this. SASA appears to play some role in adjusting the sensitivity of the oscillator to changes in light intensity. A mutation in *Synechococcus* called *CR-1* shows alteration in entrainment to light–dark cycles, and so a CR-1 protein may play a role in clock resetting. However, at this time, the photopigment underlying cyanobacterial entrainment has not been definitively identified.

overexpressed, then the subsequent levels of kaiB and kaiC are reduced and the oscillation suppressed. Overexpression of *kaiA* acts to increase the transcription of *kaiBC,* while disruption of *kaiA* lowers levels of *kaiBC*. Therefore, kaiC appears to act as a repressor of its own transcription, forming the negative feedback part of the circadian cycle, with kaiA acting as an activator and the positive limb of the circadian mechanism. Yeast two-hybrid screening was performed to

isolate additional proteins capable of interacting with kaiC. This screen led to the isolation of *sasA*, believed to be similar to sensory histidine kinases. Disruption of *sasA* dramatically lowered the amplitude of the circadian rhythm, and lowered *kaiBC* expression levels, while overexpression completely eliminated the rhythm. sasA is believed to be an additional positive regulator of *kaiBC* transcription (possibly though binding with kaiC protein), and as such forms a second positive feedback loop, which appears important for the generation of robust circadian oscillations, especially when *Synechococcus* is placed on an LD cycle. It seems likely, from previous discussions, that this negative and positive transcriptional regulation (especially that of kaiC) acts through a global change in the coiled status and structural state of the bacterial chromosome (Fig. 8). It may be of interest that the recent discussion regarding the regulation of the mammalian circadian clock, especially by Reppert and colleagues, has focused on the importance of chromatin remodeling as a critical event within the central mechanism of the mammalian clock.

3.6.3 Output

The cyanobacteria are made up of a wide range of individual species, with varying biochemical and physiological responses, and as such one should be cautious about overgeneralization. However, two clear clock-regulated outputs in these cells are the processes of photosynthesis and nitrogen fixation. These processes have conflicting physiological conditions to be performed optimally, as nitrogen fixation occurs optimally in low oxygen/anaerobic conditions. The temporal separation of these biochemical processes has a clear selective advantage, and so it is not surprising that in *Synechococcus*, therefore, photosynthesis takes place during the day and nitrogen fixation during the night. This is not true, however, for all cyanobacteria, as *Trichodesmium* shows peaks in both activities during the day. The rhythm in nitrogen fixation appears to be regulated by a nocturnal increase in nitrogenase mRNA levels in *Synechococcus*.

Perhaps, a more surprising phenomenon is that the timing of cell division also appears to be clock regulated, or to be more exact clock gated. Under conditions of rich, unlimiting media, these cells can divide as rapidly as once in every 6–10 h (so up to three times per circadian cycle). When the rhythm in bioluminescence is measured in these ''subconfluent cultures,'' amazingly, a strong circadian rhythm in gene expression can still be measured. The amplitude of this rhythm increases during the exponential phase of cell growth (probably due to an increase in cell number) and then stabilizes during the sustained phase of growth. As these cells are dividing at a much higher rate than the period of the clock, the exact phase of the rhythm must be inherited by daughter cells, which keep the oscillation running in perfect synchrony. Moreover, when the stage of the cell cycle is examined by flow cytometry, it becomes clear that the exact timing of cell division is restricted or gated to certain times of the day. On an LD cycle, *Synechococcus* cells only divide during the day and not at night. When placed into continuous light, cell division is blocked during the early subjective night, but can occur during the late subjective night and subjective day. A direct link between the clock machinery and the regulation of the cell cycle mechanism must, therefore, occur to allow for such ''gated'' regulation. It is

tempting to speculate, of course, that the influence of kaiC on DNA structure may play an important role in the regulation of this event.

The number of mutants and the ease with which bacteria can be grown has allowed for an interesting series of experiments to be performed, examining fitness under differing lighting regimes. Three strains of *Synechococcus* were used, wild type with a period of 25 h, C28a with a long period of around 30 h, and C22a with a short period of 23 h. Importantly, when grown as isolated cultures, no difference in growth rate between the differing strains was detectable. The three strains were then mixed together and placed on one of the three differing T-cycles: either an 11L:11D, 22-h day; a 12L:12D, 24-h day; or a 15L:15D, 30-h day. In all the situations tested, the strain that grew optimally and outcompeted the other strains was the one whose endogenous period most closely resembled that of the environmental light–dark cycle. So, C22a was the most competitive on a 22-h day, growing better than wild type, while C28a (with an endogenous period of 30 h) was most successful when grown on a 30-h day. The mutant phenotypes were clearly not generally impaired varieties, being much better adapted than wild types to the abnormal lighting conditions. Exactly how this improved fitness or competitive advantage is conveyed to each strain is not clear. Though, speculation includes the fact that the expression of *psbA1* is mistimed (incorrectly phased) when on deviant light–dark cycles and that this suboptimal phase angle might lead to relatively less efficient photosynthesis and, therefore, growth rates. The importance of an endogenous clock, even to organisms as ''simple'' as bacteria, has finally been demonstrated.

4 General Conclusions and Future Perspectives

The study of circadian rhythms has benefited from the interest of researchers with diverse backgrounds who have studied different groups of organisms. This broadly comparative approach has allowed results in one species to guide the development of experiments in other groups, and as a result, progress on the study of circadian rhythms has advanced across a fairly broad taxonomic front. This has been particularly true for the study of the molecular basis of the clock. As discussed above, several of the genes involved in the circadian clock in the mouse and *Drosophila* have been conserved between these highly divergent organisms. This conservation has not only aided the hunt for additional clock molecules but has had important implications for understanding clock evolution. The fact that *Drosophila* and mice share homologous clock genes suggests that there was not only a clock some 700 million years ago in the common ancestor of insects and mammals but that this clock was built along broadly similar lines to the circadian clocks we find in animals today. If we look back beyond the animal branch of the evolutionary tree and examine the molecular basis of the clock in plants, fungi, or even photosynthetic bacteria, the genes identified thus far bear no real resemblance to any of the clock genes in animals. They are not homologous, leading to the suggestion that the biological clock may have evolved multiple times during the course of evolution. It is important to stress, however, that although different sets of genes seem to generate the clock in animals, plants, fungi, and bacteria, they use the same fundamental mechanism – an ''autoregulatory negative

feedback loop'' involving several genes. It is these circadian feedback loops that have formed the central focus of the discussion in this article.

Although the basic mechanisms of the molecular clock seem to be in place, the devil is in the details. The very complexity of the models that are emerging, with their cycles and epicycles of positive and negative drives and feedback loops, resemble to some the ungainly Ptolemaian versions of the solar system! There are some very serious questions about the orthodox explanations of the circadian mechanisms that we have described. For example, clock genes probably have other functions; indeed, the primary role of some of the genes we have described may not be as elements of the clock. It has been assumed that clocks have been built from special proteins dedicated to time keeping. This may not be the case. Roenneberg argues that it is critical to consider that before clocks there had to be complex metabolic networks that were driven by light and temperature and that these metabolic pathways may still be closely associated with or even embedded within the clock. Mutant screens would never identify such metabolic genes as ablation or mutation would result in death. The orthodox models that we have described may not be wrong; the genes are clearly critical for clock function, but we cannot exclude the possibility that the clock is the product of interacting metabolic elements and the genes that we have described are epiphenomena and part of a fine-tuning mechanism.

Freedom is something that most humans strive for in one form or another. In advanced industrialized societies, the freedom to sleep, work, eat, drink, or travel when we want is becoming a real option for many, and generally applauded. But the freedom to do whatever we want, when we want, has brought an appreciation that we are not free of the ticking of our biological clock. The biological order that the clock imparts means that we are unable to perform with the same efficiency throughout the 24-h day and we ignore our biology at our peril (Fig. 1). The emerging fields of chronotoxicology and chronopharmacology provide some of the most striking examples of the relevance of circadian physiology to our daily lives. In studies of a chemical food additive tested in nocturnal mice for potential carcinogenicity, the additive appeared to be perfectly safe and approved for human use. However, the test were undertaken at 12:00 h, corresponding to the midresting phase in the mice, and at which time the rate of DNA synthesis in the liver was at its lowest and least susceptible to a potential carcinogen. When the same dose was administered at 24:00 h, the midactivity phase of mice and crucially the time of maximum DNA synthesis in the liver, 40% of the animals developed liver cancers. Because physiology is dynamic, the response of an organism to any manipulation must take the time of day into account. This knowledge is already being exploited in the treatment of cancer, where differences in the timing of cell division of host and tumor cells may be exploited to maximize treatment efficacy and minimize adverse side effects. The importance of circadian rhythms in cancer therapy is reinforced by a recent link between clock genes and cell-growth control in long-term studies of mPer2 mutant mice. These animals appear unusually cancer prone as well as susceptible to γ-radiation. A number of genes involved in cell cycle regulation and tumor suppression appear deregulated in mPer2 mutants, suggesting that this component of the molecular

clock may be vital in DNA damage responsive pathways.

A recent study by Toh et al. has provided an additional connection between the seemingly disparate worlds of molecular clocks and medicine, with the identification of a mutation in *hPer2* associated with Familial advanced sleep phase syndrome (FASPS). This condition is characterized by a shortened circadian period and an advanced sleep phase. Individuals go to bed on average at 21:00 h and wake at 05:00 h. It is remarkable that this dramatic change in behavior appears to arise from a single serine to glycine substitution in the human *Per2* gene, which yields a protein much less effectively phosphorylated by CK1ε. Similarly, two recent studies have suggested that diurnal preferences may be linked to *hPer3*, either via a repeat motif or a polymorphism within this gene. This latter study also located a polymorphism in the *NPAS2* gene, which appears to provide a link between circadian rhythms and seasonal affective disorder. Recent advances in the study of narcolepsy have provided additional clues as to how sleep–wake behavior may be driven from molecular components. The discovery of a class of neuropeptides termed *orexins (hypocretins)* involved in both regulating food intake and wakefulness may provide an additional target of clock output. In narcoleptics, deficiencies of the orexin system lead to excessive daytime sleepiness, cataplexy (spontaneous sleep episodes, often, at times of heightened emotional arousal), and hypnagogic hallucinations (presleep dreamlike episodes).

Our emerging understanding of the molecular basis of circadian rhythmicity is in identifying compelling links between a variety of human illnesses and the molecular components of the clock. This understanding will not only provide us with the means to correct these defects but also the means to manipulate normal circadian rhythms to allow us to function under abnormal temporal conditions. Edward O. Wilson stated: ''Homo sapiens, the first truly free species, is about to decommission natural selection, the force that made us. . .. Soon we must look deep within ourselves and decide what we wish to become.'' Shortly, we will have to make some moral choices. We are a diurnal species living in a 24-h world and subject to our chronobiology. We need to ask the question: should we use pharmacological or light treatments to alter patterns of gene and protein expression to manipulate the biological consequences of working at night, and embrace fully the 24/7 society, or should we reject this trend and use the knowledge of our internal temporal structure to become ''time-wise''. Should temporal freedom be something we should strive for or reject?

Keywords

Codon and Anticodon
The specific sequence of three nucleotides on the mRNA (codon) and the complementary sequence on the tRNA (anticodon).

Decoding
The mechanism by which the ribosome finds the correct aminoacyl-tRNA based on codon–anticodon interaction.

Elongation Factors
Proteins involved in the elongation of the growing peptide chain.

Exit Tunnel
The tunnel in the large ribosomal subunit for the exit of the nascent peptide chain.

Initiation Factors
Proteins involved in the translation initiation steps, that is, the initial association of the two ribosomal subunits and the binding of the first tRNA.

Molecular Chaperones
Proteins that help other proteins to fold and/or prevent aggregation.

Nascent Peptide
The growing peptide still connected to the ribosome as peptidyl-tRNA.

Peptidyl Transferase Reaction
The elongation of the polypeptide chain by one amino acid.

Release Factors
Proteins required for the release of the nascent peptide when a stop codon is encountered on the mRNA.

Translocation
The movement of the mRNA and the tRNAs through the ribosome during translation.

Translocation Machinery
Accomplishes the transport of the nascent polypeptide through the membrane or its integration in the membrane.

Abbreviations

A, P, E sites:	aminoacyl, peptidyl, exit sites
CryoEM:	cryo-electron microscopy
EF-G:	elongation factor G
EF-Tu:	elongation factor Tu
GTP:	guanosine triphosphate
mRNA:	messenger RNA
rRNA:	ribosomal RNA
SRP:	signal recognition particle
tRNA:	transfer RNA

The code for the amino acid sequence of proteins is translated by the ribosome using messenger RNA as the template. Ribosomes are RNA-protein complexes built of two subunits. In prokaryotes, the ribosome consists of a large 50S and a small 30S ribosomal subunit. Both subunits together form the 70S ribosome, the prokaryotic translation machinery. Structures of both ribosomal subunits have been solved at near-atomic resolution. The large ribosomal subunits are from the halophilic archaebacterium *Haloarcula marismortui* and from the eubacterium *Deinococcus radiodurans*. The small subunit has been solved from the thermophilic eubacterium *Thermus thermophilus*. Structures of the ribosomal subunits were also determined in complex with various antibiotics, substrate analogs, and two translation initiation factors. Finally, the entire 70S ribosome from *T. thermophilus* with mRNA and tRNAs is available at 5.5 Å as a molecular model. This wealth of structural data allows for a detailed understanding of the molecular mechanism of peptide synthesis by the ribosome.

The two most important steps in protein synthesis are the recognition of the cognate aminoacyl-tRNA and the peptidyl transfer reaction. These two functions are allotted to the two subunits of the ribosome. The small subunit mediates the interactions between tRNAs and the mRNA and selects for the correct tRNA in the decoding center. The large subunit comprises the peptidyl transferase center and provides the exit tunnel for the growing nascent polypeptide chain. The crystal structures of the separated subunits reveal many mechanistic details of the peptidyl transfer and decoding. The structures show unequivocally that mainly ribosomal RNA is present in the peptidyl transferase center as well as in the decoding center, indicating that it is in fact ribosomal RNA that is responsible for all aspects of peptide synthesis. In other words, the ribosome is a ribozyme.

Here, we analyze the crystal structures of prokaryotic 50S and 30S subunits and the intact 70S ribosome with respect to their function and describe how our understanding of the mechanism of translation has been influenced by these recent structures. Furthermore, we outline the impact of cryo-electron microscopic studies (cryoEM) on our knowledge of ribosome conformational flexibility and ribosome complexes with translation factors.

1
A Macroscopic View of Peptide Synthesis

Aminoacyl-tRNAs are the substrates for protein synthesis. They all have an L-shaped structure with the anticodon loop at the end of the long L-arm. The anticodon sequence is part of the anticodon loop and complementary to the cognate mRNA base triplet (codon). At the 3′ end of the short L-arm, the acceptor stem has a terminal CCA sequence to which individual amino acids are attached by aminoacyl-tRNA synthetases. In the cell, a specific aminoacyl-tRNA synthetase exists for each amino acid, catalyzing the formation of an ester bond between the carboxyl group of the amino acid and the 2′ or 3′ hydroxyl group of the 3′ adenosine of tRNA with the appropriate anticodon.

Both ribosomal subunits have three binding sites for tRNA, called the *A* (*aminoacyl*), *P* (*peptidyl*) *and E* (*exit*) *sites*. During protein synthesis, the tRNA anticodons interact with the mRNA and the small ribosomal subunit, while the respective aminoacyl-acceptor stems extend into the large subunit where the peptidyl transfer reaction occurs (Fig. 1). In the *decoding center* of the small ribosomal subunit,

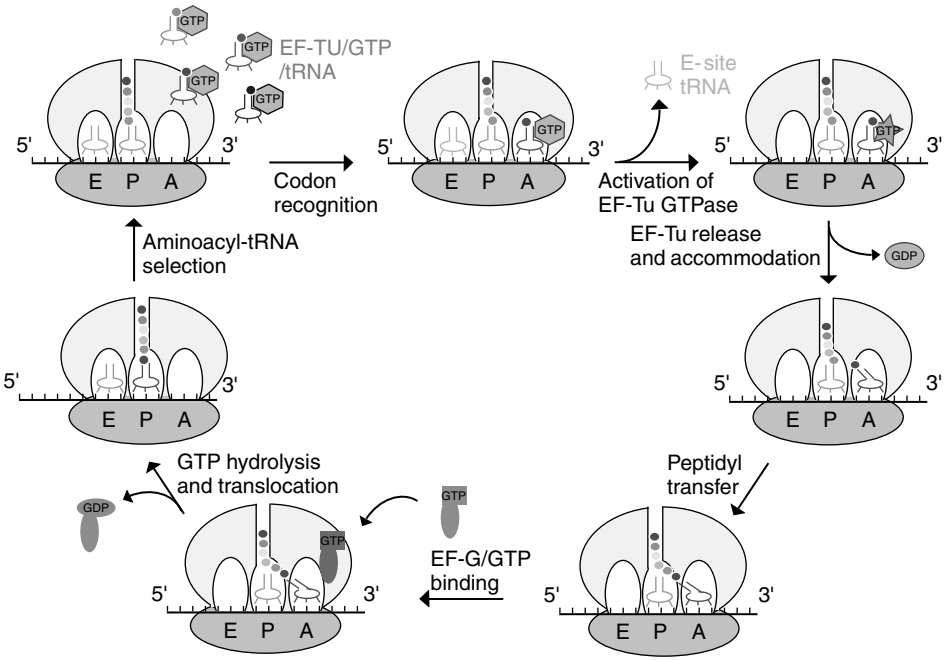

Fig. 1 Overview of the translation cycle. The cognate aminoacyl-tRNA is selected in the A site of the small subunit. The tRNA binds as a ternary complex together with EF-Tu and GTP. Binding of the cognate aminoacyl-tRNA induces GTPase activity of EF-Tu. The release of EF-Tu and GDP is followed by a conformational change of the aminoacyl-tRNA such that it binds in the A site of the peptidyl transferase center. The elongating chain is then transferred from the P-site peptidyl-tRNA to the amino group of the A-site aminoacyl-tRNA. The peptide chain leaves the peptidyl transferase center through the ribosomal tunnel, which spans the large subunit. EF-G catalyzes GTP hydrolysis and thereby drives translocation, that is, transport of the mRNA, the deacylated tRNA from the P to the E site and the peptidyl-tRNA from the A to the P site.

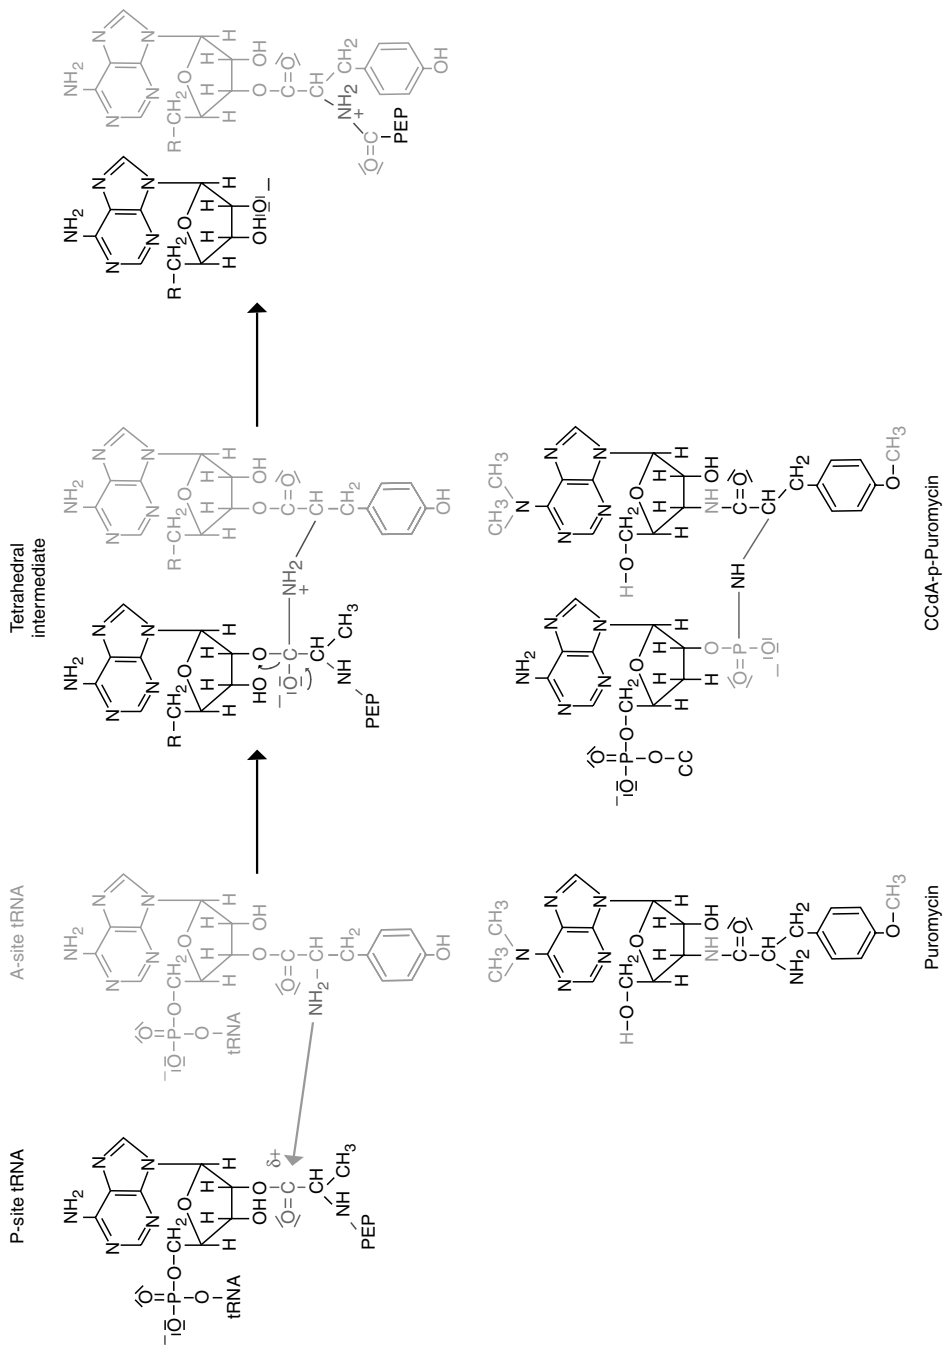

Fig. 2 (See the legend on next page)

selection of the correct aminoacyl-tRNA occurs based on the interaction of the mRNA base triplet with the anticodon triplet of the aminoacyl-tRNA. Aminoacyl-tRNAs bind to the ribosome in complex with elongation factor Tu (EF-Tu) and GTP. These ternary complexes bind tightly to the ribosome only if the anticodon matches the mRNA codon (*initial selection*). Then, GTP is hydrolyzed, resulting in release of phosphate and EF-Tu in complex with GDP (Fig. 1). Concomitantly, a large conformational change of the A site aminoacyl-tRNA occurs, referred to as *accommodation*. This positions the 3′ end of the aminoacyl-tRNA in the *peptidyl transferase center* adjacent to the P site–bound peptidyl-tRNA. Subsequently, the α-amino group of the aminoacyl-tRNA bound in the A site attacks the ester group of the peptidyl- (or N-formyl methionine initiator) tRNA in the P site at its carbonyl atom (Fig. 2). This nucleophilic attack results in a tetrahedral intermediate. A new peptide bond is formed by displacement of the P-site tRNA hydroxyl group from this intermediate (Fig. 2). As a result, the tRNA in the A site carries the nascent peptide chain, which is extended by one amino acid. The synthesized nascent peptide chain diffuses from the peptidyl transferase center into the *tunnel* and exits at the opposite side of the large ribosomal subunit (Fig. 1).

Before the next cycle of peptidyl transfer can occur, the peptidyl-tRNA has to be transported from the ribosomal A site to the P site. Furthermore, the deacylated tRNA in the P site is moved to the E site of the ribosome. This complex concerted movement of tRNAs and mRNA through the ribosome is termed *translocation*. It occurs with high accuracy and involves both subunits. The energy for translocation is provided by GTP hydrolysis catalyzed by elongation factor G (EF-G, Fig. 1). The tRNA bound in the E site interacts still with both ribosomal subunits; it is only released when the next aminoacyl-tRNA is accommodated in the ribosomal A site. A cartoonlike overview of the catalytic centers of both ribosomal subunits is given in Fig. 3.

Fig. 2 Mechanism of peptide bond formation catalyzed in the peptidyl transferase center of the large subunit. (a) The ribosomal peptidyl transferase reaction. The substrates of the peptidyl-transferase reaction are aminoacyl-tRNA and peptidyl-tRNA binding to the ribosomal A site and P site respectively. The α-amino group of the aminoacyl-tRNA in the A site of the ribosome attacks the carbonyl carbon atom of the ester bond that links the nascent polypeptides to P site–bound tRNAs. Thereby, a tetrahedral intermediate is formed at the carbonyl group with a chiral carbon atom (D) and a negatively charged oxygen. The 2′ (or 3′) OH group of the tRNA 3′-adenosine is the leaving group of the tetrahedral intermediate, and a new peptide bond (amide bond) is generated, resulting in a peptidyl-tRNA in the A site extended by one amino acid and a deacylated tRNA in the P site. (b) Puromycin resembles the 3′ terminus of tyrosyl-tRNA, and it binds to the A site of the ribosome without the need for any elongation factors. Subsequently, the peptide is transferred to the puromycin and the nascent chain is released. (c) The Yarus inhibitor (CCdA-p-Puromycin) is formed by coupling the 3′ OH group of CCdA (in the P site) to the amino group of puromycin (in the A site) via a phosphoramide group, which mimics the tetrahedral carbon intermediate. The inhibitor binds tightly to the ribosome and inhibits peptidyl transferase activity. Important differences between the CCdA-p-Puromycin and the tetrahedral carbon intermediate formed during translation are the nonchiral phosphorus atom, the delocalized negative charge, and the missing 2′ OH group of the adenine in the P site.

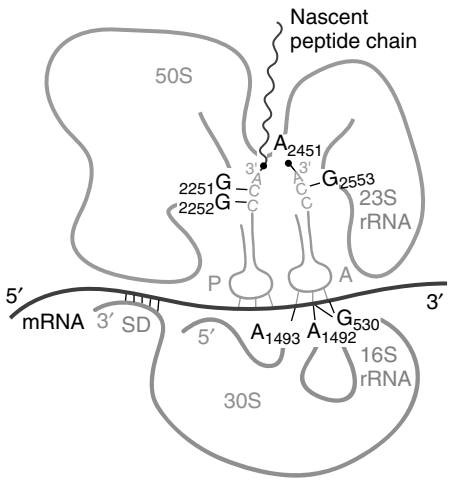

Fig. 3 Schematic overview of the ribosomal active sites. The Shine-Dalgarno (SD) sequence of the mRNA forms a helix with the complementary 3′ terminal tail of 16S rRNA. The anticodons of the A- site and P- site tRNA pair with the mRNA. In the A site decoding center of the small subunit, the codon–anticodon interaction is monitored by 16S rRNA via tertiary interactions. The tRNA acceptor stems point into the peptidyl transferase center of the large subunit. The 3′ CCA ends of the acceptor stems base-pair with 23S rRNA A-site and P-site RNA loops. The adenine of the central loop of 23S rRNA is suggested to play a role in peptidyl transfer catalysis. The nascent peptide chain is extending into the exit tunnel of the large subunit.

2
The 30S Ribosome Structure

The small subunit of the ribosome is responsible for binding mRNA and selection of the correct aminoacyl-tRNA. The structure of the small ribosomal subunit from a thermophilic bacterium *T. thermophilus* was recently determined. On the basis of electron microscopic studies, the 30S subunit is classically divided into head, body, neck, shoulder, and platform. It consists of one 16S rRNA chain and 20 ribosomal proteins (S1–S20) (Fig. 4). The shape of the small subunit is mostly determined by ribosomal RNA. The proteins are distributed over the top, sides, and back of the 30S subunit, while interface with the 50S subunit is mostly formed by rRNA (Fig. 4). Only protein S12 is located near the decoding site, whereas other proteins are found at the periphery of the subunit interface allowing them to contact the 50S subunit. Besides a globular domain many ribosomal proteins have extensions or tails that penetrate far into the rRNA core and closely interact with it, thereby stabilizing the RNA domains. The mRNA binding site and the 3′ end of 16S rRNA are situated on the platform. The tRNA binding sites are located in a cleft formed by the platform and the head (Fig. 4).

2.1
The Path of the mRNA Through the 30S Subunit

The exact path of mRNA through the ribosome was determined by X-ray crystallography of 70S ribosomes at 7 Å resolution. About 30 nucleotides of mRNA are shown to be in contact with the ribosome, predominantly with 16S rRNA. The mRNA wraps around the neck of the 30S subunit, starting with its 5′ end between head and platform and exiting on the opposite site between head and shoulder. The Shine-Dalgarno sequence, that is, the ribosome binding side provides for proper reading of the mRNA by forming a helix with the complementary 3′ terminal tail of 16S rRNA. The Shine-Dalgarno helix is located in the 30S subunit cleft between the head

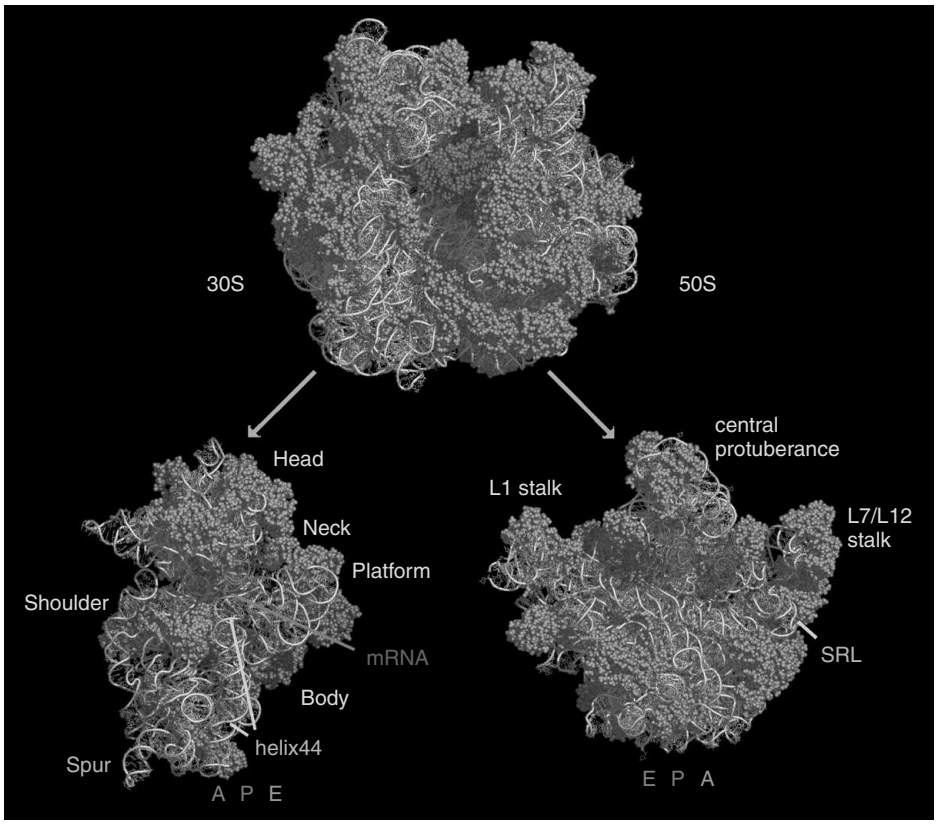

Fig. 4 Complete 70S ribosome is modeled by docking high-resolution 50S and 30S structures onto the low-resolution 70S structure. The 30S structure is from *T. thermophilus* and 50S structure from *H. marismortui* with tRNA positions determined from lower resolution 70S studies. Ribosomal RNA is depicted in gray and proteins in yellow. The 70S is shown from the side with the 30S subunit on the left and the 50S subunit on the right. In the subunit interface cavity, the tRNAs are visible. The A-site tRNA is depicted in blue, the P-site tRNA in magenta and the E-site tRNA in green. The anticodon arms of the tRNAs point to the 30S subunit, while the acceptor stems point into a large cleft in the large subunit. On the left-hand side, the 30S subunit is shown from the interface with the A-, P- and E-tRNA anticodon stem-loops. The anticodon loops of the A and P tRNAs contact the mRNA. Architectural characteristics and important features are labeled. On the right-hand side, the large subunit with tRNAs docked onto the *Haloarcula* 50S structure is shown from the interface as well. The acceptor stems of A- and P-site tRNAs point into the peptidyl transferase center. The sarcin–ricin loop (SRL) is a central part of the GTPase factor binding center. The three characteristic protuberances of the large subunit are labeled. (See color plate p. xxxviii).

and the back of the platform. From there, the mRNA enters a short tunnel, which is situated between head and platform. This region comprises the E site, which does not have full access to the interface. As a consequence, codon–anticodon interaction is not possible to the full extent for E site tRNA. Downstream of the E site, the mRNA reaches the interface by a sharp turn. On the interface, only about eight

nucleotides including the A- and P-site codons are presented to the tRNAs. There is a sharp kink in the mRNA between the codons in the A site and in the P site. This kink could play a role in maintaining the reading frame during translocation. A- and P-site codons occupy the major groove of the penultimate helix 44, which is the longest helix of the small subunit. It expands from the head to the bottom of the body and protrudes to interact with the large subunit (Fig. 4). Downstream of the A site responsible for decoding, the mRNA passes through a tunnel between head and shoulder of the subunit. Subsequently, it reaches a ring formed by proteins S3, S4, and S5 that functions probably as a helicase to remove mRNA secondary structure before entering the decoding region. During translation initiation, binding of mRNA to the small subunit requires an opening and closing of at least one of the 30S subunit tunnels at the 3′ or 5′ site of the mRNA.

2.2 Interactions of the 30S Subunit with tRNA

The three tRNAs are aligned on the 30S subunit with the anticodon loops bound in the 16S rRNA groove between the head, body, and platform (Fig. 4). In the *T. thermophilus* 30S ribosome structure, the interaction of mRNA and tRNA in the P site is mimicked through fortuitous interactions between neighboring subunits in the crystal. The 3′ end of 16S rRNA, which is complementary to the Shine-Dalgarno sequence, folds back and imitates mRNA in the P site while a stem-loop structure (the spur, Fig. 4) of a neighboring molecule in the crystal mimics the anticodon loop of the tRNA. As mentioned above, the P-site codon of the mRNA binds to the major groove of a well-conserved region of helix 44. The anticodon stem-loop of the tRNA forms several hydrogen bonds to 16S rRNA. Furthermore, the ribosomal proteins S13 and S9 interact with the anticodon loop of P-site tRNA.

The *E site*, unlike the A and P sites, consists mostly of ribosomal proteins as visualized in the *T. thermophilus* 70S structure. The E site tRNA is tightly bound and interacts with 16S rRNA as well as with a number of ribosomal proteins, mainly S7 and S11. Codon–anticodon interactions are not observed in the E site.

Recently, 30S subunit structures have been solved in complex with mRNA and cognate as well as near-cognate tRNA anticodon stem-loops in the *A site*, revealing important aspects of the decoding mechanism. The A site is much shallower and wider than the P and E sites, consistent with lower affinity for tRNA. It is mainly composed of 16S rRNA with a small contribution by ribosomal proteins S13 and S12, which contact the mRNA. Importantly, parts of the 16S rRNA, that is, the 3′ major domain and helix 44 (the penultimate helix), are responsible for the functioning of the decoding center.

2.3 The Decoding Center

The error rate of translation is 10^{-3} to 10^{-4}. Thus, the ribosome must be able to discriminate cognate from near and noncognate tRNAs by screening all three codon positions for correct interactions. This high translation fidelity cannot be explained by the difference in free energy between correct and incorrect base pairing of the codon–anticodon helix, since the free energy of some mismatches is very similar to the base pairing of cognate tRNAs. For instance, the gain of free energy of GU base pairing is very similar to the gain of AU pairing. In addition, AU

base pairing is energetically less favorable than GC pairing, that is, the gain of free energy is not the same for all cognate codon–anticodon interactions.

Moreover, the difference in free energy does not explain why the recognition of the third base pair is sometimes less stringently recognized than the preceding two. Consequently, a *wobble* can be observed in the pairing of the third base of the codon, giving rise to part of the degeneracy of the genetic code. Therefore, some tRNAs can recognize two or three codons with differences in the third base. It is clear that the *difference in free energy* of correct and incorrect base pairing may well contribute to the accuracy of translation, but by itself it cannot provide a satisfactory explanation.

As a second source of selectivity, the ribosome is capable of recognizing deviations from the Watson-Crick *base-pair geometry*, that is, the suboptimal shape of the sugar-phosphate backbone or the minor and major grooves in mismatched pairs. This sensitivity of the ribosome with regards to base-pair geometry is in analogy to enzyme *substrate recognition*.

The complex between 30S subunit, mRNA and the tRNA anticodon stem-loop switches from the open to the closed conformation if the codon–anticodon interaction is cognate. This conformational change involves flipping out of two adenines, A1492 and A1493, of helix 44. Theses adenines then tightly pack in the minor groove of the first two base pairs of the codon–anticodon helix. Both adenines form hydrogen bonds with the 2′ ribose hydroxyl groups of the codon–anticodon base pairs: a motif termed ''A-minor'' (Fig. 5). These types of tertiary interactions involving the two adenines are not possible if the codon–anticodon base pairing is noncognate, that is, not a Watson-Crick pair. Similarly, DNA polymerase and RNA polymerase use specific arginine and glutamine residues in their active center, which recognize the shape of Watson-Crick base pairs via the minor groove. A third residue, guanine530, is positioned on a loop that belongs to the 30S subunit shoulder and interacts with the second and the wobble-position base pair (Fig. 5). Consistent with the wobble base pairing in this position, the interaction of G530 with the third base pair is less sensitive to mismatches than the interaction described above involving the two adenines. The structure of 30S subunit, mRNA, and a cognate anticodon stem-loop shows that upon binding of the cognate tRNA, G530 flips from a *syn* to an *anti* conformation (Fig. 6). Near-cognate tRNA (with a single mismatch) does not cause flipping out of the adenines or G530. Consistent with their important role in decoding, A1492, A1493, and G530 are universally conserved and essential for cell viability.

In summary, the ribosome precisely monitors the minor groove geometry of the codon–anticodon interaction at the first two positions in the A site. Therefore, codons that differ in the first or second base but encode the same amino acid must pair with different tRNAs. The third position allows mismatches, which explains the frequent appearance of inosine in the anticodon at this position. Inosine can pair with cytosine, adenine, and uridine, thus maximizing the number of codons recognized by the specific tRNA molecules.

The close contacts of the cognate codon–anticodon pair with A1492, A1493, and G530 induce a characteristic closing of the 30S subunit around the A site. This locking up involves conformational changes of the overall 30S architecture. In particular, these are rotations of the

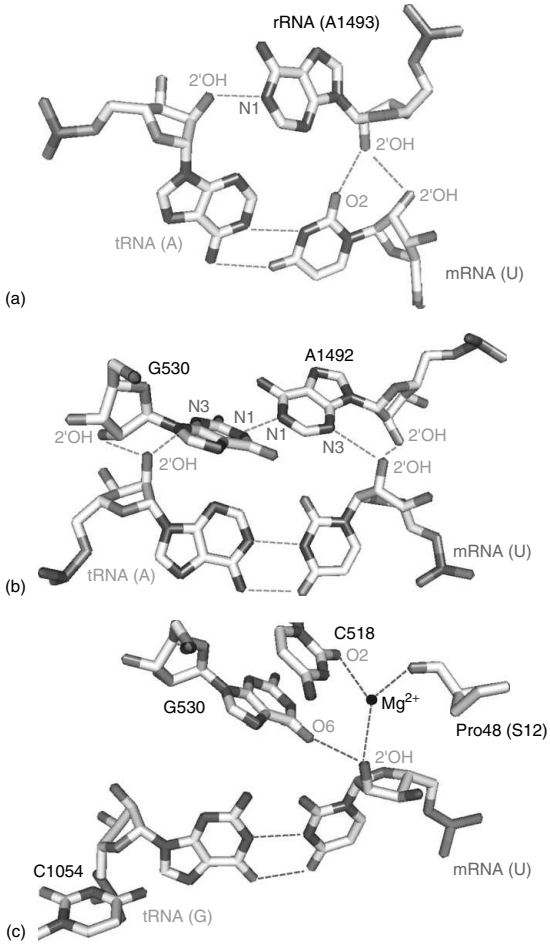

Fig. 5 Monitoring of the codon–anticodon interactions in the decoding center. (a), (b), and (c) show the minor groove recognition at the first (a), second (b) and third base position (c) respectively. (a) Adenine1493 binds into the minor groove of the first AU base pair. It forms hydrogen bonds to the 2′OH group of the tRNA with its N1 atom and to the 2′ OH group of the mRNA base with its 2′OH group. An additional hydrogen bond is formed between the 2′OH group of A1493 and the O2 group of uracil in the mRNA. (b) In the second position, A1492 and G530 both bind into the minor groove of the codon–anticodon helix and form hydrogen bonds with their N1 atoms. A1492 interacts with the 2′OH group of the mRNA via its N3 and 2′OH group. G530 also forms two hydrogen bonds with its 2′OH and N3 and the 2′OH group of the tRNA respectively. (c) The third base pair is monitored less stringently (wobble position). O6 of G530 forms a hydrogen bond to the 2′OH group of the mRNA. A second, magnesium ion-mediated interaction occurs between the 2′OH group of the mRNA and O2 of C518, as well as the main chain carbonyl of proline48 of protein S12. The GU mismatch is not selected against at this third position.

head toward the shoulder and the subunit interface, as well as movement of the shoulder toward the interface and the platform. Particularly well characterized is the ''helix 27 accuracy switch'' during the transition to the closed conformation. In this case, the packing of helix 27 to helix 44 changes because of a disrupted RNA turn. Thus, the structure of the decoding center is altered. Noncognate and near-cognate tRNA binds to the open conformation and cannot induce closing of the 30S subunit. In the closed conformation, the aminoacyl-tRNA cannot leave the A site. In conclusion, *induced fit* is a further source of accuracy, in addition to the A1492-, A1493-, and G530-based proofreading mechanism (substrate recognition) and free energy gains of codon–anticodon interaction.

During *initial selection*, the specific aminoacyl-tRNA is still bound by EF-Tu, and the acceptor stem of the aminoacyl-tRNA is not in contact with the peptidyl transferase center of the large ribosomal subunit. In cryoEM studies of the ternary complex bound to the 70S ribosome stalled with kirromycin resembling the

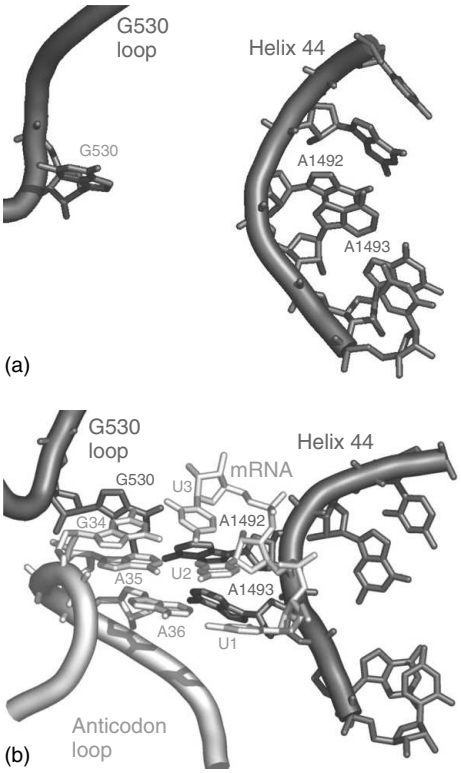

Fig. 6 (a) The empty decoding center of the native 30S subunit. The two 16S rRNA loops in the catalytic center are depicted in gray. The bases A1492 and A1493 are stacked in the helix 44 loop interior. G530 is in the *syn* conformation. (b) The decoding center in the presence of mRNA and the cognate tRNA anticodon loop. The mRNA and the tRNA anticodon loop are shown in white. A1492 and A1493 are now flipped out of helix 44 and pack tightly into the minor grove of the codon–anticodon helix monitoring the first two codon positions. G530 changes its conformation to *anti* and binds in the minor groove of the codon–anticodon helix monitoring the second and the third codon position.

GTPase activated state, tRNA adopts an unusual conformation that appears to facilitate codon–anticodon interaction. Cognate tRNA induces the closed conformation of the 30S subunit and triggers GTP hydrolysis by EF-Tu bound to the large subunit. Subsequently, the 3′CCA end of the aminoacyl-tRNA is released by the EF-Tu-GDP complex and can then rotate into the A site of the peptidyl transferase center. This *accommodation* process needs the full-size tRNA molecule, indicating that tRNA may play an active role in intersubunit signaling. Indeed, in the cryoEM studies of the kirromycin stalled ternary complex, the elbow region of the aminoacyl-tRNA could contact the GTPase associated center of the 50S subunit (while EF-Tu binds the sarcin–ricin loop) during initial selection and thus could induce GTP hydrolysis by a conformational change. However, since the data is at low resolution, it can also support a different model of GTPase activation triggered by conformational changes in both ribosomal subunits transmitted from the 30S subunit to the 50S subunit through intersubunit bridges. In fact, a significant movement of the two subunits relative to each other is observed during accommodation Accommodation can lead to dissociation of the aminoacyl-tRNA from the ribosome. This provides a *second proofreading step* during translation because the interactions between the ribosome and the codon–anticodon minor groove must be sufficiently strong to prevent the dissociation of the A site tRNA in the absence of EF-Tu. In summary, two selection stages

exist, which are separated by irreversible GTP hydrolysis.

Clearly, there is a sensitive equilibrium between the open and closed conformation of the 30S subunit during decoding, and stabilization of one or the other conformation seriously affects translation accuracy. The transition into the closed conformation reduces polar interactions present at the S4/S5 interface. Destabilizing mutations in S4 and S5 residing between the shoulder and platform facilitate the transition to the closed conformation. This results in a higher affinity for tRNA and thus in an *error-prone ribosome*. In the closed conformation, S12 can form new salt bridges to helices 27 and 44. Destabilizing mutations of the involved residues result in reduced affinity for tRNA. Thus, the open conformation is favored and the ribosome is in a *hyperaccurate state*.

2.4 Modes of Antibiotic Inhibition

Structures of antibiotics bound to both ribosomal subunits provided detailed information on antibiotic action and the mechanistic basis of antibiotic resistance. In addition, further insights into the translation process were derived from such analyses. About 20 structures of antibiotics bound to the ribosome are available to date. Most of the antibiotics examined bind to functionally important parts of the 30S subunit at or near the decoding center or at locations that are important for conformational changes during translocation. Here, we focus on two 30S subunit binding antibiotics, paromomycin and streptomycin, because the mechanism of their action can be explained with the obtained structures.

The binding of the error-inducing aminoglycoside antibiotic *paromomycin* has been structurally characterized by both, NMR using a fragment of 16S rRNA and by crystallography of the 30S subunit in complex with paromomycin, mRNA, and a near-cognate tRNA anticodon stem-loop. Paromomycin binds to helix 44 inducing a conformational change where crucial bases of the decoding center, A1492 and A1493, are flipped out of the helix and interact directly with the minor groove of the codon–anticodon helix. This is the same conformation otherwise observed upon binding of cognate tRNAs. Thus, paromomycin decreases ribosome's selectivity.

Streptomycin acts during the accommodation step by stabilization of the overall closed conformation of 30S subunit, leading to error-prone translation. Streptomycin binds tightly to helix 27, helix 44, the 530 loop, and protein S12. Resistance to streptomycin is conferred by mutations in S12 that destabilize the closed conformation of the 30S subunit, leading to a hyperaccurate state.

2.5 Translation Initiation – Interactions with Initiation Factors

The initiation factors IF1 and IF3 bind to the small ribosomal subunit. Their structures have been solved in complex with the 30S subunit. IF1 prevents tRNA binding to the A site on the 30S subunit. In the IF1–30S complex, IF1 binds to a site that includes the A site of the small subunit, that is, helix 44, the 530 loop, and protein S12. The ribosomal binding site of IF1 contains many basic residues whereas the solvent-exposed site is rich in negative charges. A loop of IF1 interacts with the minor groove of helix 44. The two adenine bases, A1492 and A1493, are flipped out of helix 44 upon IF1 binding and are buried in IF1. In addition, IF1

induces a conformational change of helix 44 and shifts the relative orientations of the 30S domains. The head, platform, and the shoulder rotate toward the A site, adopting a conformation that probably resembles an intermediate between subunit association and dissociation.

IF2 binds to the acceptor stem of the initiator tRNA, and it interacts with IF1. The IF2 GTPase domain presumably binds to the GTPase factor binding site on the 50S subunit, but direct location of IF2 has not been determined yet.

IF3 binds tightly to the 30S subunit and interferes with its association to the 50S subunit. In addition, it helps in selecting the *N*-formyl methionine-tRNA by excluding other aminoacyl-tRNAs from the P site. IF3 has two distinct domains, of which the C-terminal domain has been shown to be sufficient for 70S dissociation. The location of the C-terminal domain of IF3 in the X-ray structure of the 30S–IF3 complex is not the same as observed by cryoEM nor is it as derived from biochemical data obtained by hydroxyl radical cleavage. In the cryoEM structure, the N-terminal domain of IF3 binds to the tRNA binding cleft of the 30S subunit, whereas the C-terminal domain is found at the interface side of the platform and the neck of the 30S subunit, which is the E site. Thus, IF3 is spanning the interface region from the platform to the neck of the 30S subunit. At this position, the C-terminal domain IF3 would be adjacent to the P site and would directly interfere with subunit association. IF3 has been shown to bind to three base pairs of the anticodon stem-loop that are unique to initiator tRNA. Therefore, the C-terminal domain is probably responsible for recognizing and selecting the initiator tRNA without interfering with the codon–anticodon interaction in the P site. In contrast to biochemical and cryoEM data, IF3 was visualized at the upper end of the platform on the solvent-exposed side of the 30S subunit in the X-ray structure of the 30S–IF3 complex. In that case, the negative effect of IF3 on subunit association would have to be much more indirect, for instance, by influencing the conformational state of the 30S subunit.

In summary, IF1 binds to the A site on the small subunit, IF2 binds over the A site in complex with the initiator tRNA which occupies the P site, and IF3 binds to the ribosomal E site. Thus, in the initiation complex, all tRNA binding sites are occupied and IF2 and IF3 both select for the correct initiator tRNA.

3 The 50S Ribosome Structure

The large ribosomal subunit is mostly composed of 23S and 5S rRNA and contains approximately 31 to 35 proteins (L1–L35); the exact amount of protein is species dependent. The ribosome core is well conserved in all species and consists mainly of ribosomal RNA. The 50S structure shows three characteristic protuberances: the L1 stalk, the central protuberance, and the L7/L12 stalk (Fig. 4). The proteins are not distributed equally over the ribosome but cluster at the solvent-exposed surface. Their extensions play an important role in the stabilization of the RNA tertiary structure. Similar to the structure of the small subunit, proteins are largely absent from the functionally important sites, namely, the peptidyl transferase center and the interface. 23S rRNA forms a compact, single hemispherical domain, which is the body of the large subunit (Fig. 4). The protuberances consist of 23S rRNA, proteins L1, L7, L10, L11, and L12

and 5S rRNA in case of the central protuberance. The stalks are involved in bridges to the small subunit or interact with tRNAs or GTP-binding translation factors and thus are likely to be dynamic elements of the 50S subunit.

The first 50S X-ray structure obtained from the archaebacterium *H. marismortui* was resolved to 2.4 Å resolution (Fig. 4). The structure highlighted two paramount features of the large subunit, the peptidyl transferase center and the exit tunnel. It provided a detailed overview of the overall architecture and important information about RNA-protein interactions. Furthermore, water and metal ion positions as well as base modifications could be identified, all of which may contribute to the folding and stabilization of the ribosome. Subsequently, the *D. radiodurans* 50S structure was solved at 3.1 Å resolution. While being very similar to the archaeal large subunit, this structure provided additional information on some regions that were disordered in the *Haloarcula* 50S subunit. The disordered regions were proteins L1, L10, L11, L12, that is, components of the two lateral protuberances, the L11 RNA region, and some RNA stem-loops contacting the small ribosomal subunit. These regions are likely to be flexible in the isolated 50S subunit and could adopt a more defined conformation upon association with their binding partner. Stabilizing elements of the large ribosomal subunit are proteins, water, metal ions, and tertiary RNA interactions named A-minor motifs (as observed in the decoding center).

3.1 The Molecular Mechanism of Peptidyl Transfer

The peptidyl transferase center is located at the bottom of a large cleft in the center of the subunit interface (Fig. 4). Although there was mounting evidence that ribosomal proteins are not involved in peptidyl transfer, unambiguous demonstration that the peptidyl transferase center is entirely composed of 23S rRNA was provided with the *Haloarcula* 50S structure in complex with CCdA-p-Puromycin (the Yarus inhibitor). In fact, there is no ribosomal protein present in the proximity of the peptidyl transferase center within a distance of 18 Å. The catalytic site is formed by the highly conserved central loop (the peptidyl transferase loop) of domain V, which is located at the bottom of the cleft.

Once the cognate aminoacyl-tRNA enters the ribosomal A site of the large subunit, the peptidyl transfer occurs spontaneously, that is, without additional energy input. On the basis of the structure of the 50S subunit in complex with CCdA-p-Puromycin and a number of substrate and product analogs, several roles of the ribosome in catalysis were suggested.

First, the ribosome closely brings the two tRNAs together and orients them precisely (*substrate orientation*). The acceptor stems of the aminoacyl-tRNA (mimicked by an aminoacylated minihelix) and the peptidyl-tRNA (mimicked by CCA phenylalanine caproic acid biotin (CCApcb)) point into the cleft, and their 3′CCA ends are proximate to each other (Fig. 7). The 3′CCA sequence of the A-site tRNA interacts with the A loop (helix 92 of 23S rRNA) in the catalytic center, and the 3′CCA sequence of the P-site tRNA base-pairs with the P loop (helix 80 of 23S rRNA) (Fig. 7). The CCA sequence alone can bind to the large subunit, indicating that this is the most important interaction of tRNA with the 50S subunit. By base-pairing with the CCA ends, both RNA loops position the two acylated tRNAs precisely such that the

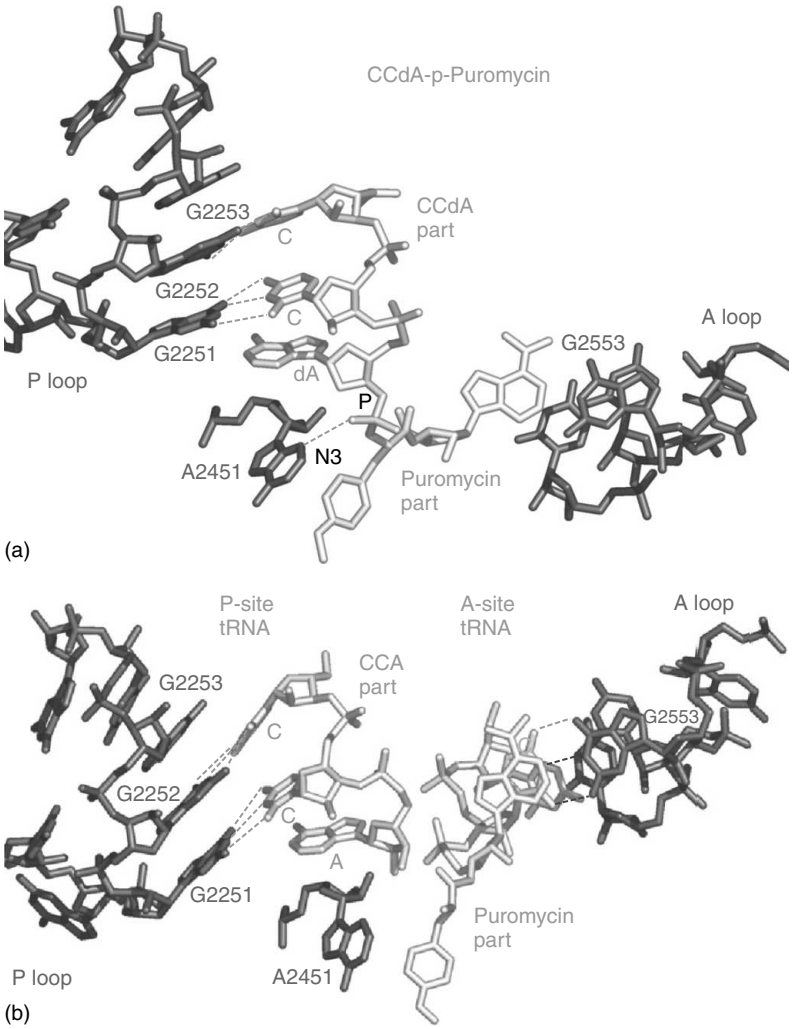

Fig. 7 (a) The structure of the peptidyl transferase center of the 50S ribosomal subunit. The A and P loop of 23S rRNA are shown in gray, the CCdA-p-Puromycin in white. The inhibitor occupies both the tRNA binding sites. The phosphoramide of the inhibitor is close to N3 of adenine2451. A2451 is part of the central loop in the peptidyl transferase center and may play a role in catalysis. (b) The peptidyl transferase center with a P-site and an A-site substrate analogs. In the P site, the cytosines of the CCA pair with two guanines G2251 and G2252 of the P loop. In the A site, the second base of CCA, the cytosine pairs with guanine 2553 of the A loop. The two substrate analogs mimic the situation in the active center immediately after peptidyl transfer.

α-amino group of the A-site aminoacyl-tRNA is close enough to the carbonyl carbon of the P-site peptidyl-tRNA for the nucleophilic attack (Fig. 2).

Second, *transition state stabilization* could lower the activation energy barrier as suggested by the 50S structure in complex with the CCdA-Puromycin inhibitor, which resembles a reaction intermediate. CCdA-p-Puromycin (Fig. 2) binds tightly to the P and A site loops and inhibits peptidyl transfer (Fig. 7a). Nevertheless, this compound is not a good analog because of the nonchiral phosphorus atom, the delocalized negative charge, and the missing 2′OH group on the CCdA part.

The third contribution to catalysis, suggested based on the *Haloarcula* structure with CCdA-p-Puromycin, could be the N3 of A2451 (*E. coli* numbering), which may participate in *acid–base catalysis*. This adenine is closest to the tetrahedral intermediate mimic of CCdA-p-Puromycin (Fig. 7a). Thus, N3 of A2451 could hydrogen-bond and abstract a proton from the amino group of the tetrahedral intermediate facilitating the release of the leaving group.

The pH-dependence of the peptidyl transfer reaction was analyzed by quench flow assays in which purified ribosomal complexes containing radioactive peptidyl-tRNA in the P site were incubated with puromycin at saturating concentrations. At pH 7.5, reaction rates of $50\ s^{-1}$ were obtained, comparable with *in vivo* protein synthesis. At lower pH, the peptidyl transfer was 100-fold slower. Taking into account the pK_a of puromycin, the data indicated the existence of a single titratable group in the catalytic center with a pK_a of 7.5. The pH effect disappeared when an A2451U mutant was analyzed and the reaction rate was decreased by a factor of 130, consistent with the idea that A2451 acts as a general base. Nevertheless, alternative explanations involving protonation of neighboring residues are also possible.

Although the role of A2451 in transition state stabilization and acid–base catalysis is unclear, it certainly plays an important role in peptidyl transfer by substrate orientation and hydrogen bond formation to the α-amino group of aminoacyl-tRNA.

3.2 The Exit Tunnel

The structure of the large ribosomal subunit reveals a tunnel spanning its entire body through which the peptide emerges while still connected to the peptidyl transferase center (Fig. 8). The tunnel is approximately 100 Å in length and has a diameter of about 15 Å. The polypeptide exit tunnel is largely formed by 23S rRNA domains I and II but shows significant contributions from ribosomal proteins L4 and L22 (Fig. 8). Approximately 28-Å apart from the tunnel, exit proteins L4 and L22 fence the most constricted part of the tunnel with a diameter of 10 Å (Fig. 9). The opening of the exit tunnel is at the bottom of the back side of the 50S subunit. The exit is encircled by proteins L19, L22, L23, L24, L29, and L31 (Fig. 10).

The tunnel can accommodate 30 to 40 amino acid residues of a growing polypeptide chain and can therefore protect it from protease digestion or immunoprecipitation with antibodies specific for a nascent polypeptide. In fact, these initial experiments led to the proposal of the existence of a ribosomal tunnel about 35 years ago. Little is known about the conformation of the nascent polypeptide in the tunnel. Since the diameter of the tunnel is 10 Å at its narrowest part, the peptide could adopt an α-helical structure,

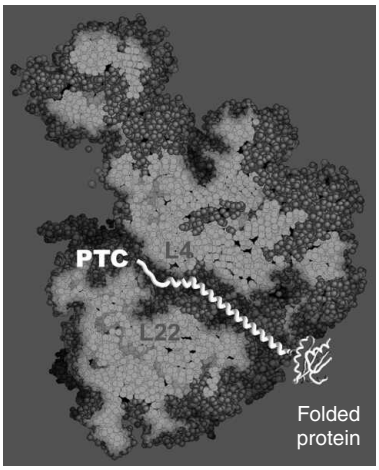

Fig. 8 The polypeptide exit tunnel. The 50S subunit is cut in half such that the tunnel is shown in its entire length. The ribosome atoms are shown in a space-filling representation. All RNA atoms that do not contact solvent are shown in white, and surface atoms are color-labeled with oxygen red, carbon yellow, and nitrogen blue. Proteins are depicted in green, and surface residues are in the same color code as RNA surface atoms. A model of a nascent chain polypeptide passing the tunnel is shown in white ribbon. The polypeptide is still connected to the peptidyl transferase center and can adopt an α-helical conformation in the tunnel. Outside the tunnel, the polypeptide chain can fold cotranslationally adopting its tertiary structure. The narrowest part of the tunnel is constricted by the two proteins L4 and L22. (See color plate p. xxxix).

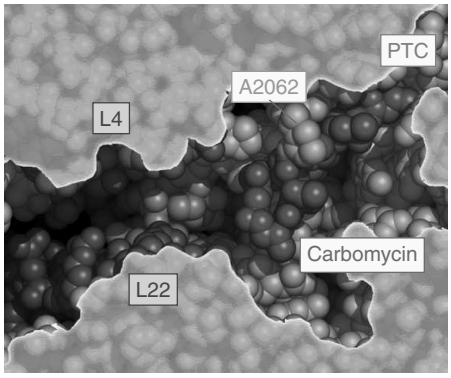

Fig. 9 A section of the ribosomal tunnel with Carbomycin A bound. The first and most constricted half of the tunnel is shown in a longitudinal section. All rRNA atoms are shown in yellow, and protein atoms of L4 and L22 are colored blue in a space-filling representation. The cutting plane is gray. The macrolide antibiotic Carbomycin A (red) is bound to the 50S tunnel blocking the passage of the nascent chain, and its disaccharide isobutyrate extension reaches to the peptidyl transferase center (PTC). A covalent bond is formed between N6 of A2062 of 23S rRNA and an ethylaldehyde substituent of Carbomycin A. (See color plate p. xxxiv).

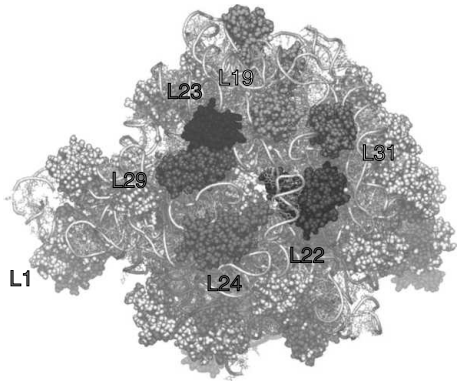

Fig. 10 The tunnel exit of the 50S subunit. Proteins at the rim of the exit tunnel are shown in the different colors. Some of the proteins are suggested to interact with the translocation machinery. L23 and L29 are implied to play a role in protein folding and transport across membranes based on their interaction with chaperones and SRP. The 23S rRNA and other ribosomal proteins are shown in white. (See color plate p. xxxvi).

which would be approximately 6 to 10 Å in diameter (Fig. 8). However, it appears to be unlikely that tertiary protein folding can occur within the tunnel although it widens toward the exit. 23S rRNA can be cross-linked to the nascent chains, although the surface of the tunnel should prevent tight binding of unfolded nascent polypeptides. The tunnel surface is largely composed of hydrophilic, noncharged groups, but no large hydrophobic patches that could form extensive interactions with exposed hydrophobic amino acids are found. Thus, because of selective pressure, the tunnel should allow the passage of any nascent protein with naturally occurring sequence.

3.3 Antibiotics Targeting the Large Subunit

The large ribosomal subunit is targeted by many antibiotics and substrate analogs. These compounds bind to the functionally important regions of the subunit such as the GTPase factor binding center, the peptidyl transferase center and the nascent polypeptide exit tunnel. Because of structural studies, detailed information of their mode of function is currently available for some of the peptidyl transferase inhibitors and the macrolide class of antibiotics.

Chloramphenicol prevents the accurate binding of aminoacyl-tRNA to the ribosomal A site. In contrast to puromycin that acts as an aminoacyl-tRNA analog, chloramphenicol interferes with the exact positioning of the aminoacyl moiety in the A site. Therefore, the formation of the tetrahedral transition state during the peptidyl transfer reaction may be hampered. In addition, the electronegative dichloromethyl group of chloramphenicol is close to the amino group of A site–bound aminoacyl-tRNA, and this may interfere with its nucleophilic attack on the carbonyl carbon atom of the ester bond that links the nascent polypeptide to the P-site anchored tRNA. The other antibiotic that interferes with substrate binding is *Clindamycin*. Binding of this compound overlaps with both A- and P site–bound substrates.

Macrolide antibiotics such as erythromycin block the diffusion of the nascent polypeptide into the tunnel. The exact binding site is found between the peptidyl transferase center and the narrowest part of the tunnel fenced by protein L4 and L22 (Fig. 9). The lactone ring of erythromycin binds with its hydrophobic face directed toward the tunnel wall forming van der Waals contacts with the tunnel surface, whereas its hydrophilic side is exposed. The sugar moieties of the macrolide form hydrogen bonds to the rRNA. Erythromycin binding reduces the diameter of the tunnel from 18 to 19 Å to less than 10 Å, thereby interfering with the path of the elongating peptide. Conversely, if the nascent chain is already in the tunnel, protein synthesis is not inhibited by erythromycin. Mutations in L4 and L22 causing an enlargement or a further constriction of the tunnel confers resistance to erythromycin. These mutations allow the passage of the polypeptide even though erythromycin is bound, or they prevent macrolide binding through conformational changes in the rRNA. Erythromycin binding does not inhibit the peptidyl transferase reaction, and the ribosome can synthesize short tri- or tetrapeptides in the presence of erythromycin. There is a clear correlation between the length of the macrolide substituent at the C5 position of the lactone ring extending toward the active center and the maximal length of the polypeptide that can still be translated. *Carbomycin A*, a macrolide antibiotic with an extended disaccharide isobutyrate

substituent on the lactone ring, interferes directly with the peptidyl transfer reaction since its extension reaches to the peptidyl transferase center. In addition to the van der Waals interactions and the hydrogen bonds, some macrolides like carbomycin A carrying an ethylaldehyde substituent on the C8 position can form a reversible covalent bond with N6 of A2062 (Fig. 9).

3.4 Regulatory Nascent Chains

It was recently discovered that certain polypeptide chains interact with the ribosomal exit tunnel. This contradicts the idea that the tunnel is a neutral environment for the exit of polypeptides and indicates that there is interaction between certain nascent peptides and the tunnel, which can regulate the rate of translation. Tight interaction between the nascent chain and the ribosomal tunnel leads to stalling of protein synthesis.

Such a stalling sequence motif was discovered at the C-terminus of the SecM (secretion monitor) protein of *E. coli* by mutational studies. It was determined that a particular sequence motif of 17 amino acids FxxxxWIxxxxGIRAGP is sufficient to cause ribosomal stalling. A genetic screen for stalling suppressor mutants revealed that the SecM peptide interacts tightly with 23S rRNA at the entrance of the exit tunnel and with protein L22 at the narrowest constriction of the tunnel, which is interestingly the same region in which macrolide antibiotics bind (Fig. 9). Accordingly, the stalling motif can be transferred from SecM to other proteins and causes translational arrest as well.

The real function of SecM is regulation of SecA expression through its N-terminal export signal. In the presence of abundant SecA, an ATPase, which is part of the translocation machinery, the stalled SecM peptide is ''pulled'' out of the ribosomal tunnel and delivered to the translocon. The basis of this regulation is a dicistronic mRNA encoding SecM and SecA, with a strong RNA stem-loop occluding the ribosome binding site of the secA gene. When SecA is missing, translation of the upstream secM gene causes ribosomal stalling, which resolves mRNA stem-loop and permits initiation of secA translation. In the presence of abundant SecA, translational arrest is abolished and the Shine-Dalgarno sequence of the secA gene is inaccessible for the ribosome, preventing SecA synthesis. Remarkably, interactions between the stalling sequence and the ribosome is so strong that overexpression of the SecM stalling sequence without the N-terminal signal sequence, recognized by SecA, is lethal for *E. coli*.

These results demonstrate that the exit tunnel is not a passive environment for the nascent chain. In fact, there are increasing number of effector sequences that either interfere with protein elongation or translation termination. The individual effector sequences share little sequence homology, although several sequences have positively charged residues, which could interact with ribosomal RNA, and the C-terminal residue is frequently a proline.

A distinct mechanism of translational arrest is mediated by binding of the signal recognition particle (SRP). When the translated polypeptide chain has a signal sequence at the N terminus, this sequence is recognized by SRP. The binding of the SRP to the ribosome-nascent chain complex causes a translation arrest, which is resolved only when the peptide binds to the translocon. The stalling effect could either result from a conformational change of the active site of the GTPase factor binding center upon SRP binding to the

ribosome, or it could be transmitted in a more subtle way through the peptide itself.

3.5 The GTPase Factor-Binding Center

The elongation factors EF-Tu and EF-G, as well as the other GTP-binding translation factors such as initiation factor IF2 and release factor RF3 interact with the large ribosomal subunit. The location of the GTPase domain binding site, named factor binding center, is known from cryoEM studies. The factor binding center includes the highly conserved *sarcin–ricin loop* (stem-loop 95 of 23S rRNA, Fig. 4), which is absolutely essential for factor binding. Ribosomes can be inactivated by the cleavage of a single covalent bond in the sarcin–ricin stem-loop. The rest of the factor binding region is formed by proteins L14, L23, and L6 on the body of the 50S subunit and proteins L11, L10, and L7/L12 on the flexible stalk. Conformational changes of the ribosome and the elongation factors upon GTP-hydrolysis were visualized by cryoEM. Sequence comparisons of EF-Tu, EF-G, IF2, and RF3 suggest that they all contain two domains with a similar fold that are responsible for binding to the GTPase activating center. This implies that they all bind to the ribosome in a similar fashion.

3.6 Structural Mimicry

Crystallographic studies revealed a *structural mimicry* of the ternary complex comprising tRNA, EF-Tu and GTP and EF-G : GTP. The tRNA shape is almost perfectly mimicked by the three domains of EF-G. This mimicry was further supported by cryoEM data of EF-G bound to the A site on the ribosome.

In fact, several proteins have been identified with a similar shape as the tRNA including release factors eRF1 and RF2, the ribosome recycling factor (RRF), and the tetracycline resistance protein. Clearly, there is also *functional mimicry* between aminoacyl-tRNAs and release factors RF1 and RF2, since both bind to the ribosomal A site, recognize specific mRNA codons, and simultaneously interact with the peptidyl transferase center. In prokaryotic RF1 and RF2, triplets of aminoacids have been identified that are responsible for the RF specificity. In eukaryotic eRF1, which recognizes all three stop codons, a highly conserved sequence motif has been identified as the ''anticodon'' serving region. It is assumed that the decoding regions of RFs directly interact with the mRNA codon in the ribosome. However, the detailed decoding mechanism of stop codons and the discrimination against sense codons by RFs is still unclear. The catalytic mechanism of peptide release is another unsolved question. Genetic studies suggest that the mechanism of peptide release is distinct from peptide formation but involves 23S rRNA as well.

The final step in translation termination is the disassembly of the ribosomal complex and recycling of the ribosomal subunits. This step is supported by EF-G and RRF, which is a nearly perfect mimic of tRNA.

4 The 70S Ribosome Structure

The *T. thermophilus* 70S structure at 5.5 Å, containing mRNA and three tRNAs, sheds light on the interactions between the 50S and 30S subunit (Fig. 4). In comparison to the isolated subunits, 70S ribosomes show certain conformational differences, most

of them stem directly from intersubunit association. Some flexible regions of the 50S structure are ordered in the 70S ribosome, indicating that these elements may adopt a defined geometry upon 30S association.

4.1 The 30S–50S Interface

The 70S structure reveals a network of intermolecular bridges involving RNA–RNA and RNA–protein interactions as well as a single protein–protein interaction. Mobile *intersubunit bridges* are suggested to play a major role in translocation because they allow movement of the ribosomal subunits with respect to each other. Viewed from the interface, ribosomal proteins are mainly located at the periphery of the 30S and 50S subunits (Fig. 4). The interface consists predominantly of RNA: twelve individual intersubunit bridges were identified, most of which are RNA helices. These contacts mostly involve minor groove–minor groove interactions. The RNA bridges are located in the center of the interface, on the 30S platform and helix 44, adjacent to the tRNA binding sites. Contacts involving proteins are peripheral to the functional sites. One of the most important intersubunit contacts seems to be the centrally located flexible bridge element formed by interaction of helix 69 of 23S rRNA with helix 44 of 16S rRNA at the base of the decoding center. Breakage and formation of many of these interface bridges probably accompanies translocation.

4.2 Translocation – The Concerted Movement of tRNAs and mRNA

After peptidyl transfer, the empty P-site tRNA and the peptidyl-tRNA in the A site have to move in concert with the mRNA. Several models have been proposed for translocation. Widely accepted is the *hybrid state model*, which involves independent tRNA movement with respect to the two subunits (Fig. 11). Pursuant to this model, tRNAs can occupy different tRNA binding sites on the small and large subunit, corresponding to a hybrid state. On the small subunit, the mRNA moves in complex with the tRNA anticodon stem-loops, while the acceptor stems of the tRNA are fixed in their respective binding sites on the large subunit (Fig. 11).

Chemical footprinting and cryoEM was used to monitor the movement of tRNAs through the ribosome. Following peptidyl transfer, it was found that the 50S A-site tRNA footprint disappeared and a 50S E-site tRNA footprint emerged instead. At the same time, the tRNA footprints on the small subunit did not change. The hybrid state model suggests a transition into a state in which the former A-site tRNA (A/A) still occupies the A site on the small subunit but its acceptor stem moved into the P site on the large subunit (A/P hybrid state). Concomitantly, the former P-site tRNA (P/P) still forms codon–anticodon contacts in the P site of the small subunit but, at the same time, moves away from the peptidyl transferase center on the large subunit into the E site (P/E hybrid state). This rearrangement is independent of EF-G. In cryoEM, only a small movement of the A-site acceptor stem toward the P site is visible after the peptidyl transfer reaction. In the *Haloarcula* 50S structure, the peptidyl-tRNA remained bound to the A loop in the peptidyl transferase center (the loop that binds A-site aminoacyl-tRNA, Fig. 7b). The P/E hybrid state has been observed by cryoEM, but only under stringent buffer conditions.

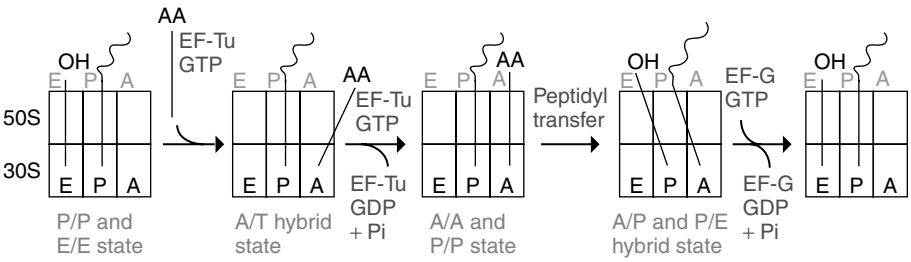

Fig. 11 The hybrid state model for translocation. The tRNAs move independently within the active sites of the two ribosomal subunits. Translocation from the A/T hybrid state into the A/A state depends on GTP hydrolysis by EF-Tu. Translocation into the P/E and A/P hybrid state occurs spontaneously after peptidyl transfer. In contrast, the translocation of the tRNAs and mRNA within the small subunit from the P/E : A/P hybrid states to the E/E : P/P state requires GTP hydrolysis by EF-G.

Upon incubation of the A/P and P/E hybrid state with EF-G and GTP, the tRNAs move to the P/P (occupying the P site on both subunits) and E/E site (Fig. 11), as evidenced by chemical footprinting. This means that upon GTP hydrolysis, EF-G induces tRNA movement with respect to the 30S subunit whereas movement with respect to the 50S subunit occurs spontaneously after peptidyl transfer. Curiously, GTPase activity of EF-G is not essential since translocation can still occur in the presence of nonhydrolyzable GTP analogs, although at a slower rate.

A third type of hybrid state (the *A/T hybrid state*, T for EF-Tu) is observed when the ternary complex of EF-Tu, GTP, and tRNA binds to the ribosome (Fig. 11). In chemical footprinting studies, this complex of tRNA EF-Tu and GTP-protected 16S rRNA in the 30S A site, but there was no tRNA footprint in the 50S A site. Instead, bases in the sarcin–ricin loop in the GTPase factor binding center of the 50S subunit were protected in a similar fashion as upon EF-G binding. After EF-Tu GTP hydrolysis and accommodation, the 50S A site becomes occupied by tRNA.

A prerequisite for a hybrid state is the mobility of the two subunits relative to each other or at least of parts of the subunits. Indeed, it has been observed by cryoEM that the two subunits can rotate 6° relative to each other upon EF-G binding. Following EF-G dependent GTP hydrolysis, translocation occurs, coupled with EF-G release and simultaneous back-rotation of the 30S subunit relative to the 50S subunit. In addition to subunit rotation, regions of the ribosomal subunits, such as intersubunit bridges, could move together with the tRNAs during translocation.

What exactly could be the driving force for the translocation in the 50S subunit? First, the peptidyl transferase reaction could directly provide the free energy for spontaneous translocation from the A/A state to the A/P state. Second, the tRNA binding sites on the large subunit could have different substrate specificities. In that case, the A site would have highest affinity for aminoacyl-tRNA, the P site a higher affinity for peptidyl-tRNA and the E site for deacylated tRNA. The latter possibility would explain the directionality of the process. There is evidence that peptidyl transfer and translocation occur in a sequential manner on the large subunit. Contrariwise, the translocation of tRNAs and mRNA on the small subunit

requires energy input. The movement of the tRNA from the A/A state to the A/P hybrid state could decrease the affinity of the tRNA–mRNA helix for the small subunit. This would result in lower activation energy for translocation on the small subunit, provided that the affinity of tRNAs and the bound mRNA for 16S rRNA really presents an energy barrier for the movement between the tRNA binding sites on the small subunit. Moreover, if EF-G binding and GTP hydrolysis depend on a hybrid state of the ribosome, the coupling of peptidyl transfer reaction and translocation would be ensured.

4.3 Movement of tRNAs through the Ribosome

In the 70S structure, the tRNAs are in A/A, P/P, and E/E states rather than in any hybrid state. The large subunit makes contacts with the conserved structures of the tRNA, that is, the tRNA D-stem, elbow, and acceptor arm. The A and P site tRNAs are closest to each other at their acceptor stems, which are within 5-Å vicinity. In the small subunit, the anticodon ends of the tRNAs and the mRNA move only 20 to 28 Å between the A and P site or P and E site respectively. At the same time, the acceptor stem moves over much larger distances in the large subunit. For instance, the E site acceptor stem is rotated away from the P-site tRNA acceptor stem and directed into a separate cleft nearly 50 Å away from the peptidyl transferase cavity (Fig. 4). The L1 stalk and protein S7 seem to lock the deacylated tRNA in the E site as evidenced by the 70S X-ray structure. In the free 50S structure, the L1 stalk has an open conformation, in which it would not prevent release of E-site tRNA. A large rotational movement of tRNA is also necessary during its accommodation from the A/T hybrid state into the A site of the peptidyl transferase center.

4.4 Cotranslational Folding

Upon leaving the tunnel, the peptide chain can fold into its tertiary structure while still being bound to the ribosome. Cotranslational folding has been demonstrated, *in vitro* and *in vivo*, as well as in eukaryotic and prokaryotic cells. For large multidomain proteins, folding in a sequential manner may be beneficial to the folding process to avoid interference between individual protein domains during early folding steps. In the tunnel, the nascent polypeptide can adopt α-helical conformation (Fig. 8), but the diameter of the tunnel does not allow significant tertiary structure formation beyond that. Depending on the amino acid sequence of the nascent polypeptide, a different extent of secondary structure in the tunnel is acquired as indicated by different patterns of cross-linking to 23S rRNA. Moreover, depending on the sequence, different lengths of nascent polypeptides (30–72 amino acids) are protected by the ribosome, suggesting a varying extent of secondary structure formation. The opening of the tunnel is surrounded by ribosomal proteins L19, L22, L23, L24, L29, and L31 and regions of 23S rRNA. These elements may assist in protein folding (Fig. 10).

During translation, the ribosome-nascent peptide chain complexes can interact with various proteins involved in protein targeting and folding, for instance, molecular chaperones like the trigger factor, DnaK/DnaJ/GrpE in *E. coli*, and their homologs in eukaryotes. *Trigger factor*, a cis/trans prolyl isomerase that has protein-folding activity, was shown to be associated

with the large ribosomal subunit when binding the nascent chain polypeptide. The N-terminal domain of trigger factor was identified as a ribosome binding domain. It could be cross-linked to proteins L23 and L29, which are located adjacent to each other at the tunnel exit site, exactly where the nascent chain emerges from the tunnel (Fig. 10). By mutational studies, it was shown that ribosome association is essential for trigger factor chaperone activity *in vitro* and *in vivo* and that an exposed, conserved glutamate (E18) of L23 protein is critical for the binding. Thus, ribosomal protein L23 directly links protein synthesis with chaperone-assisted folding.

4.5 Protein Secretion and Membrane Insertion

The ribosome participates directly in the transport of nascent chains into or across membranes to the periplasm or endoplasmic reticulum. Most of the secreted proteins contain an N-terminal hydrophobic signal sequence recognized by the *SRP*. Helicity as well as hydrophobicity of the *signal sequence* are necessary for the productive interaction with SRP and the translocation machinery. SRP binds and targets the ribosome-nascent chain complex to its receptor in the membrane. Subsequently, SRP hands over the ribosomal complex to its receptor, which coordinates the release of SRP from the ribosome-nascent chain complex and the insertion of the nascent chain into the translocation channel, which is built up by the Sec61 complex in eukaryotes and by SecYEG in prokaryotes.

In eukaryotes, SRP is composed of a 7S RNA and six proteins. The 54 kD protein SRP54 has been identified to bind the signal peptide and to interact with the signal receptor. SRP54 can be cross-linked to the large ribosomal subunit in the presence and absence of a nascent chain. Thus, this is clearly the ribosome binding domain of SRP. The two adjacent ribosomal proteins L23 and L35 (L29 in *E. coli*), both located at the rim of the tunnel exit, are the binding partners of SRP54, (Fig. 10). SRP proteins SRP9 and SRP14 are required for the SRP induced translational arrest (as discussed earlier). The nascent chain is released when SRP54 binds GTP and interacts with its receptor. The SRP receptor induces changes in the SRP binding to the ribosome and permits access of the translocation channel to the ribosome-nascent chain complex, such that the signal peptide is handed over to the Sec61 complex and translation continues. In the presence of SRP, direct binding of the Sec61 complex to the ribosomal complexes is blocked.

The structure of the eukaryotic ribosome-nascent chain complex and the eukaryotic *translocation machinery* Sec61 has been studied by cryoEM. The Sec61 complex consists of three transmembrane subunits α, β, and γ, comprising 12 transmembrane helices altogether. Three or four Sec61 complexes assemble to form the functional ringlike translocon with a central pore or indentation. The ringlike Sec61 complex binds to the large ribosomal subunit such that its central pore is aligned with the opening of the protein exit tunnel. Thereby, a path for the nascent chain is formed from the peptidyl transferase center directly into the endoplasmic reticulum. Four connections were identified between the Sec61 complex and the ribosome-nascent chain complexes in the 15-Å cryoEM structure. They involve mostly ribosomal RNA (28S) but also involve the eukaryotic homologs of the ribosomal proteins L19,

L23, L24 and L29 (Fig. 10); the region next to the tunnel exit is relatively conserved in prokaryotes and eukaryotes. The most substantial connection is found for proteins L23, L29, and helix7 of the rRNA. It is interesting to note that L23 and L29 are also implied to play a role in trigger factor and SRP binding, and this may be the reason why deletion of L23 is lethal.

The binding of the translocation machinery to the ribosome leaves a gap between ribosome and the transmembrane channel of at least 15 Å. This finding contradicts earlier postulations that the translocon/ribosome interface should form an ion-tight seal. The cryoEM structure suggests that the channel itself is the permeability barrier between cytoplasm and lumen.

Cotranslational folding also occurs during translocation of proteins into the endoplasmatic reticulum. The minimum distance between the folded domain and the peptidyl transferase center was determined to be 64 amino acids. This agrees well with the protection of 70 amino acids from proteolysis and the minimal peptide length of 70 amino acids needed for glycosylation by the glycosylase in the ER at the exit of the translocon pore. All biochemical and structural data support the idea that the translocon channel extends the ribosomal exit tunnel, even though there appears to be a gap between them. The translocon is probably a dynamic complex, since it allows lateral diffusion of the nascent chain into the membrane bilayer, which probably requires opening of the channel ring.

5 Perspectives

Recent crystal structures improved our understanding of the mechanism of protein synthesis. The peptidyl transferase reaction and the accuracy of aminoacyl-tRNA selection can now be studied with detailed structure-based experiments (Fig. 3). However, many questions remain to be addressed on a molecular level. Especially since information about intersubunit interactions, conformational changes during translation and interaction with translation factors originate from low-resolution structures. Ultimately, all relevant intermediates, complexes, and conformational states of the ribosome should be characterized at high resolution to completely understand translation and associated processes like cotranslational folding and translocation across the membrane.

Functionally important regions of the ribosome including the decoding center, the peptidyl transferase center, and the tunnel are highly conserved. Therefore, it is likely that the fundamental mechanism of translation is the same in all kingdoms of life. Most differences in the architecture of the eukaryotic 80S ribosome compared to the 70S ribosomes are generated by additional proteins and RNA insertions into the periphery of the structure. Nevertheless, eukaryotic translation is much more complex and subjected to a more diversified regulation. Extracting structural information on the eukaryotic ribosome will be undoubtedly difficult, but the task is well worth the extraordinary effort.

Keywords

Exon
The sequences within a gene or an RNA transcript that are represented in the final mature RNA product of a gene. Before RNA splicing, exons are separated by introns.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 12
Edited by Robert A. Meyers.

ISBN: 3-527-30649-8

Intron
An internal sequence of nucleotides within a gene or an RNA transcript that is removed by RNA splicing before the formation of the functional RNA product.

Polymerase Chain Reaction (PCR)
A method utilizing a DNA polymerase and primers complementary to each end of a targeted DNA region to produce multiple copies of a double-stranded DNA sequence.

Reverse Transcriptase
An enzyme, derived from retroviruses, that copies RNA sequences to produce DNA.

Ribonucleoprotein
A macromolecular complex comprising both RNA and protein.

Ribozyme
An RNA molecule that is endowed with catalytic activity; for *ribo*nucleic acid en*zyme*.

RNA Processing
The biochemical reactions the primary RNA transcript of a gene must undergo before it can become a mature, functional RNA.

RNA Splicing
The removal of intron sequences and joining of exons to generate a mature RNA molecule.

Self-cleaving RNA
An RNA molecule that is capable of cleaving itself in a site-specific manner.

Ribozymes are RNA molecules that can function to catalyze specific intracellular chemical reactions without the obligatory participation of proteins. Until recently, all biochemical reactions were believed to be catalyzed by protein enzymes. Since 1982, a number of RNA molecules have been found to be endowed with catalytic activity. For example, group I ribozymes take the form of introns, which can mediate their own excision from a self-splicing precursor RNA. Other ribozymes are derived from self-cleaving RNA structures that are essential for the replication of viral RNA molecules. Like protein enzymes, ribozymes can fold into complex three-dimensional structures that provide specific binding sites for substrates as well as cofactors, such as metal ions. Ribozymes have been developed into highly specific enzymes that are capable of recognizing and catalytically cleaving targeted RNA molecules. A wide variety of activities can be elicited from ribozymes by selection, and targeted ribozymes have been used scientifically and therapeutically to cleave viral RNAs and messenger RNAs associated with disease.

1
RNA Can Encode Genetic Information, Participate in Translating it, and also Catalyze Biochemical Reactions

RNA is a unique molecule in the biological world because it serves several fundamentally distinct functions. It has long been known that RNA, like DNA, can serve as an informational molecule. For example, messenger RNA transcripts carry the information encoded by genes to the cell's protein synthesis machinery. Many viruses, like HIV and influenza, use RNA as their genetic molecule. Transfer RNAs help decode the information from messenger RNAs, and ribosomal RNAs are large, essential functioning components of the ribosomes, the cellular machines that produce proteins by translating messenger RNAs.

More recently, investigators have found that some RNA molecules resemble protein enzymes in that they can catalyze specific biochemical reactions. The discovery that RNA can be a catalyst has revolutionized our view of RNA and its importance, and it has led to the speculation that catalytic RNA may have played a critical role in the prebiotic evolution of self-replicating systems.

2
RNA Structure and Catalysis

The catalytic activity of ribozymes results from the three-dimensional folded structure of RNA. Because RNA is a single-stranded molecule, it can fold into structures much more complex than the monotonous structure of the DNA double helix. Much is known about the secondary structure of ribozymes (Fig. 1), which generally consists of a number of short intramolecular helices composed of Watson–Crick G–C and A–U base pairs, separated by nonhelical segments. There are computer applications that can predict likely secondary structures for given RNA sequences. It is clear that the nonhelical segments of ribozymes are very important for catalytic activity; these nonhelical nucleotides interact with one another to form a tertiary structure. They may also provide functional groups that help catalyze biochemical reactions.

Recent advances in X-ray crystallography of RNA have provided three-dimensional crystal structures for several small ribozymes. In at least two of these cases, the crystal structures correlate well with biochemical data, showing how important residues of the ribozyme are positioned very close to the cleavable linkage of the target RNA, in such a fashion that functional groups from the ribozyme could be helping to catalyze the chemical reaction. These crystal structures also help explain why some catalytic RNAs can function without divalent ions like magnesium. Magnesium helps in folding RNA to its tertiary structure, but some ribozymes function well in high concentrations of monovalent ions like sodium. This is important because it shows that these catalytic RNAs do not function merely by positioning a magnesium ion to catalyze a reaction. Instead, the catalytic function is performed by chemical groups on the RNA itself.

RNA differs from DNA in the presence of a 2′-hydroxyl group on the sugar of each nucleotide. This functional group may be important for catalytic activity in three respects. First, it makes RNA much more chemically labile than DNA. Second, it participates in essential tertiary interactions within ribozymes that are essential for catalytic activity. Third, it

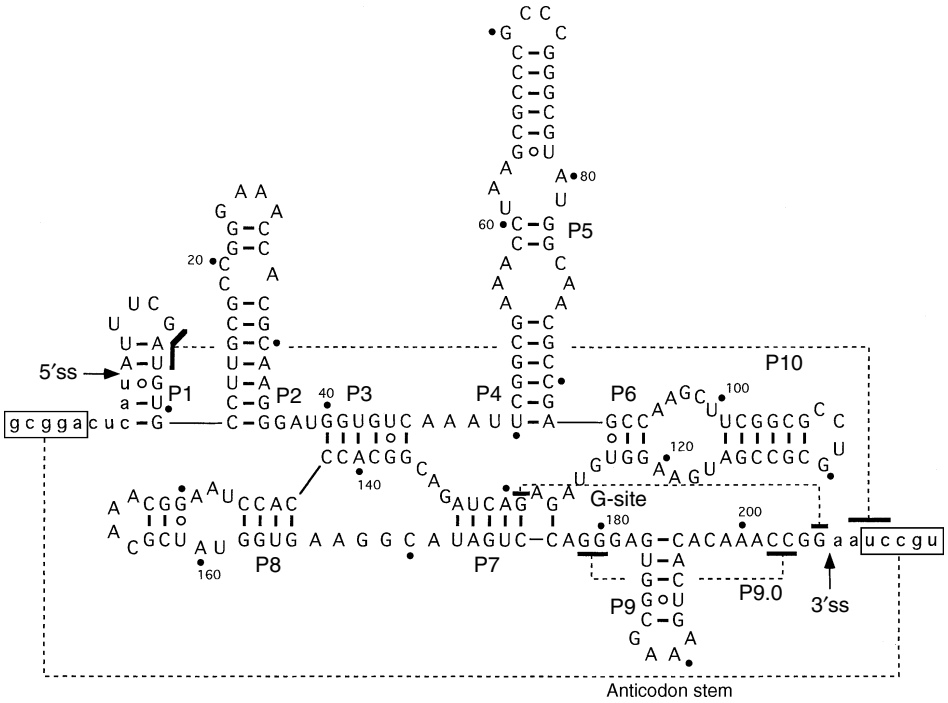

Fig. 1 The secondary structure of a self-splicing group I intron within a transfer RNA precursor of the bacterium *Azoarcus*: arrows indicate splice sites, intron and exon nucleotides are indicated in uppercase and lowercase letters respectively. All group I introns have very similar RNA folding patterns. The RNA folding is responsible for catalytic activity and for the precise identification of the reaction sites.

may participate directly in the chemical reactions that take place at the active site of the ribozyme.

3 New Understanding of the Importance of RNA in Biological Systems

In recent years, investigators have discovered important new biological roles carried out by RNA in cells and organisms. In eukaryotes, small interfering RNAs (siRNAs) only about twenty nucleotides in length, derived from double-stranded RNAs, serve as guides to target enzymatic degradation of foreign RNA and viral messenger RNAs. Small cellular species called *micro RNAs* (miRNAs) interact with messenger RNAs to modulate their translation during development.

In bacterial systems, Breaker and colleagues discovered RNA motifs called *riboswitches* at the leading ends of important messenger RNAs. These motifs bind specific small molecules, often the products of the enzymes produced from the messenger RNA. Binding of this metabolic product to the RNA motif changes its folding pattern and decreases its expression, either in transcription or translation, creating a negative feedback control at the level of RNA. One of these riboswitches is actually a new small ribozyme, which,

upon binding its specific small ligand, becomes activated to cleave its own messenger RNA.

Recent studies of ribosomes (see the following) have shown that the actual chemical reaction joining amino acids to form a new protein is almost certainly carried out by the RNA component of the ribosome rather than by protein, as previously assumed. Moreover, there is good preliminary evidence that RNA may also catalyze the splicing steps that remove introns from messenger RNAs in eukaryotic nuclei. In summary, RNA has more active and important roles in biology than were previously understood. Ribozymes, rather than being evolutionary oddities, are central players in the biochemistry of life.

4 Self-splicing RNA

The first catalytic RNA molecules discovered were self-splicing RNA molecules containing group I introns. In the absence of proteins, these molecules can undergo rapid and precise structural rearrangements to excise the intron and covalently join the exons. Group I introns contain characteristic internal nucleotide sequences and have very similar RNA folding patterns (Fig. 1); these common structural features are essential for catalytic activity and for recognition of the correct reaction sites in the precursor RNA.

Splicing of precursor RNAs containing group I introns occurs by a two-step reaction pathway (Fig. 2). In the first step, GTP attacks the 5′ splice site, becoming covalently linked to the intron and liberating the 5′ exon. In the second step, the 5′ exon attacks the 3′ splice site, joining the exons together and liberating the intron RNA. It is clear that the intron RNA itself contains the catalytic center, because it can catalyze additional reactions on internal and external RNA substrates. A second class of self-splicing introns, the group II introns, is known. These introns share common folded structures and reaction pathways that are distinct from

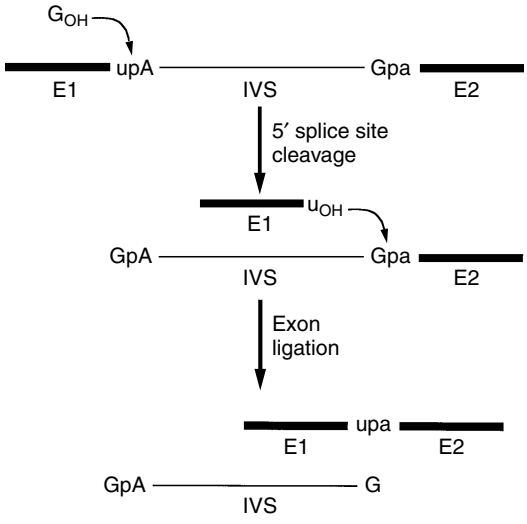

Fig. 2 RNA splicing pattern for group I introns. First, GTP or another guanosine attacks the 5′ splice site, liberating the 5′ exon and becoming covalently linked to the intron. Second, the 5′ exon attacks the 3′ splice site in a reaction that generates ligated exons and liberates the intron. Each of these transesterification reactions can take place in the presence or in the absence of proteins.

those of group I introns. Interestingly, group II introns appear to be more closely related to the nuclear pre-mRNA introns, whose splicing is catalyzed by complex nuclear particles called *spliceosomes*. As mentioned in Sect. 3, there is some evidence that the chemistry carried out by the spliceosome may be catalyzed by one or more of the small nuclear RNAs contained in it.

5 Self-cleaving Catalytic RNA

In addition to their importance for RNA splicing, catalytic RNA molecules are essential for RNA replication in some viral systems. For example, a circular RNA molecule associated with tobacco ringspot virus is replicated by a rolling-circle mechanism, as shown in Fig. 3. Site-specific RNA cleavage and joining reactions are essential for RNA replication. Instead of using protein ribonucleases and RNA ligases as catalysts, these reactions are carried out by the RNA molecules themselves.

That is, during replication the RNA molecules contain sites at which the cleavage and joining reactions happen, as well as domains that recognize those sites and catalyze the reactions. A similar replication pathway is followed by the RNA genome of an important human pathogen, hepatitis delta virus.

Deletion of the nonessential RNA sequences serves to isolate the catalytic domains and the sequences that are recognized and cleaved. The catalytic domains function as ribozymes to cleave the substrate in a catalytic manner; that is, each ribozyme molecule can potentially cleave a large number of substrate RNA molecules.

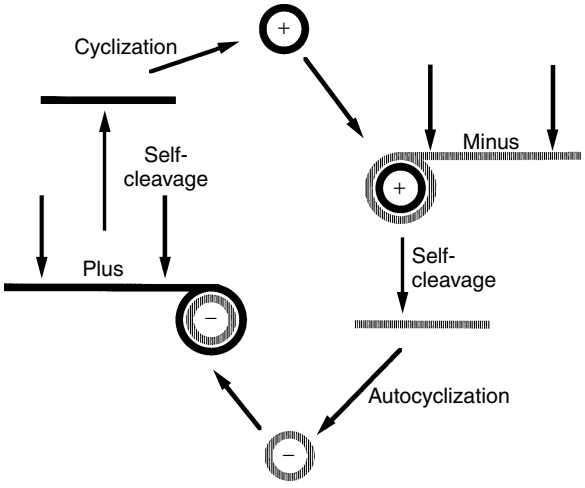

Fig. 3 Self-cleaving RNA in RNA replication: the replication pathway for the satellite RNA associated with tobacco ringspot virus. Rolling-circle replication gives rise to linear negative- and positive-stranded concatemers that must be cleaved and cyclized at specific sites. The self-cleaving domains in the positive and negative strands are known as the hammerhead ribozyme and the hairpin ribozyme, respectively.

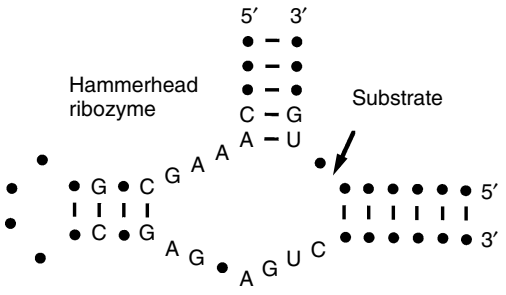

Fig. 4 The secondary structure of the complex between the hammerhead ribozyme and its substrate: arrow indicates cleavage site; essential bases are indicated by letters; one dot indicates that any base can function at the specified position; two dots joined by a line indicates that any base pair will function. The substrate may be a short RNA oligonucleotide for laboratory biochemical studies, or it may be a part of a long RNA molecule (e.g. a cellular mRNA or viral genomic RNA molecule).

The hammerhead ribozyme is one of the smallest ribozymes derived from self-cleaving RNA molecules. The secondary structure of the ribozyme–substrate complex (Fig. 4) consists of one intramolecular duplex within the ribozyme domain and two intermolecular duplexes between the ribozyme and substrate. Because the sequence of the intermolecular duplexes can vary in any manner that maintains base pairing, the hammerhead, and other small ribozymes can be engineered to bind and cleave new RNA targets such as messenger RNAs or viral RNAs. They have proven useful as tools for inhibiting expression of specific genes, and some have reached clinical trials as antiviral therapeutics.

Three of the small ribozymes, the hammerhead, hairpin, and hepatitis delta ribozymes, have been characterized by X-ray crystallography. For two of them, the hairpin ribozyme and hepatitis delta ribozyme, the crystal structures seem to represent active conformations. The ribozymes fold into complex three-dimensional structures that force the cleavable bond into an orientation favorable for catalysis, and they position functional groups of important nucleotides in the ribozyme close enough to help facilitate the cleavage reaction.

6 Ribonucleoprotein Enzymes: The Ribosome is a Ribozyme!

Many cellular RNAs are bound to specific proteins, forming ribonucleoprotein (RNP) complexes. These RNPs are responsible for catalyzing a number of critical cellular functions. For instance, ribosomes are RNP complexes responsible for synthesizing proteins from a messenger RNA template. The spliceosome is an RNP complex that splices intron-containing messenger RNA precursors within the eukaryotic nucleus.

The bacterial ribonuclease P (RNase P) is a particularly interesting and well-studied example of an RNP enzyme. This enzyme cleaves the 5′ extension from precursor transfer RNA molecules (Fig. 5), yielding the mature 5′ end of all the different tRNAs in the cell. RNase P consists of a fairly large RNA subunit plus a small basic protein. *In vitro*, in high salt, the RNA subunit can carry out the correct cleavage reaction within the protein.

Investigators have gained much insight into the structure of the RNase P RNA through phylogenetic analysis – that is, through comparison of the nucleotide sequences of this RNA isolated from many different bacterial species. Many sequence positions vary between species, but often

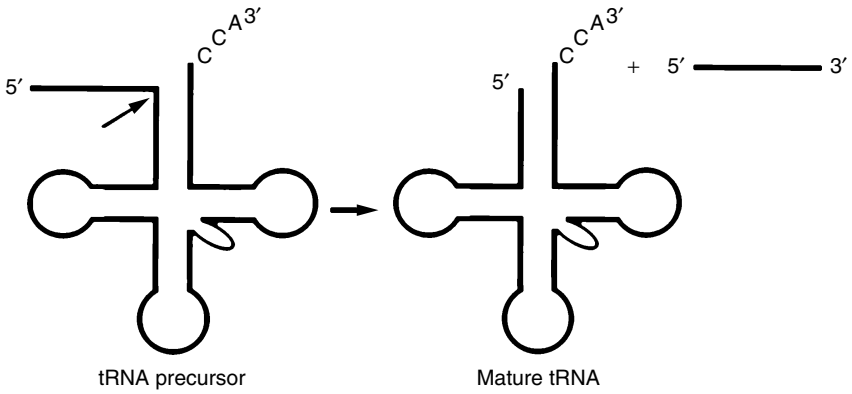

Fig. 5 Reaction catalyzed by Rnase P. Newly transcribed tRNA precursors contain 5′ extensions. Rnase P cleaves these extensions from all tRNA precursors, generating the mature 5′ end for the tRNA molecules.

they ''covary,'' as necessary to maintain the base pairing of a stem. Other sequence positions essential for activity may be conserved in many different species. Such phylogenetic comparisons of RNase P RNA have yielded a ''consensus'' sequence (Fig. 6), which shows the minimal essential secondary structure of the RNA plus conserved sequences that participate in tertiary interactions required for enzymatic activity.

The story of the RNA-mediated activity of the ribosome is a finding particularly exciting for biological scientists. Ribosomes consist of two subunits, ''large'' and ''small,'' each containing at least one long RNA molecule and scores of proteins. The large ribosomal subunit was known to carry peptidyl transferase, the activity that transfers amino acids from their transfer RNA carriers to the growing peptide chain in protein synthesis. Recently, the large ribosomal subunit was crystallized, and the structure of the enormous complex was characterized by X-ray diffraction to very fine resolution. The region shown to be involved in peptidyl transferase activity consists entirely of RNA, with no ribosomal proteins located close enough to be participants. This and other results confirm that the chemical step of protein synthesis is catalyzed by RNA: in other words, the ribosome is a ribozyme. This finding reinforces the possibility that the early stages in the evolution of life involved an ''RNA world,'' in which RNA served both to carry genetic information and to catalyze many of the chemical reactions essential for a self-replicating system.

7 *In Vitro* Selection

A recently developed set of methods provides powerful tools for analyzing the structure–function relationships of existing ribozymes and also makes it possible to create and ''evolve'' new ribozymes that carry out desired chemical reactions. These methods are analogous to the procedures of genetic selection, but they can be carried out on RNA without the need for a host cell.

The first step in *in vitro* selection (Fig. 7) is the production of a large pool, or

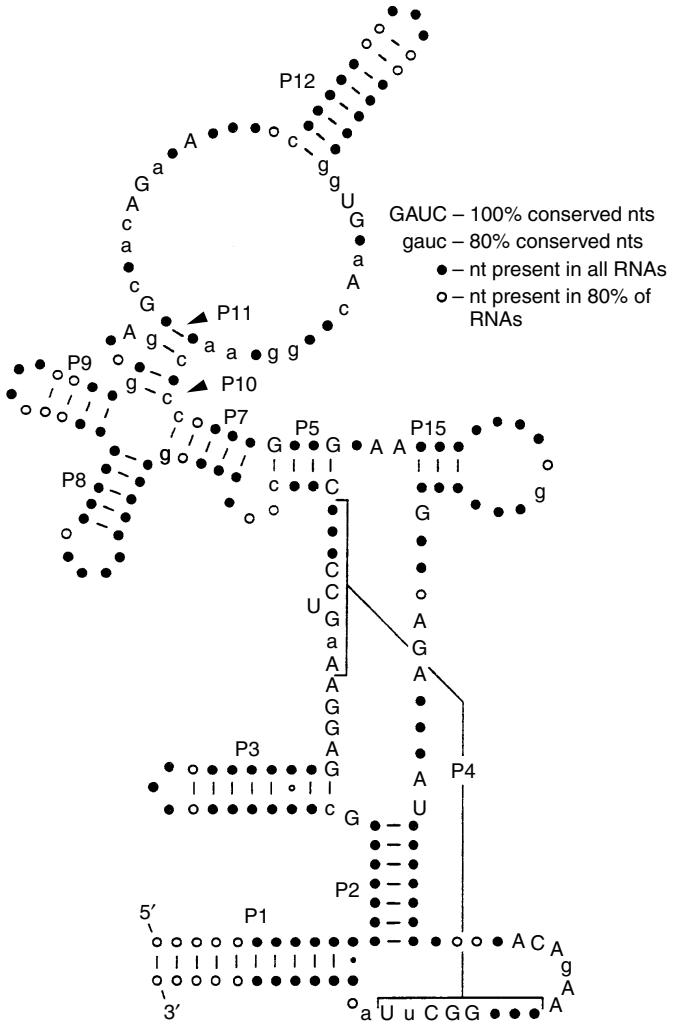

Fig. 6 Phylogenetic minimum bacterial consensus Rnase P RNA: helices are labeled (P1, P2 etc.); base pairs in P2 are shown as brackets and lines. Only the structural elements present in all known bacterial RNAse P RNAs are included in the minimum structure. Universally conserved nucleotides are in uppercase. Nucleotides not conserved in identity but present in all sequences are indicated by solid circles; those present in at least 80% of sequences, but absent in at least one, are indicated by open circles.

population, or RNA molecules with a region of randomized sequence. If the molecules are chemically synthesized, a position can be randomized by providing a mixture of all four nucleotide precursors at synthesis instead of one particular nucleotide. Then this population of molecules is provided with the opportunity to catalyze a chemical reaction. The reaction is designed to permit

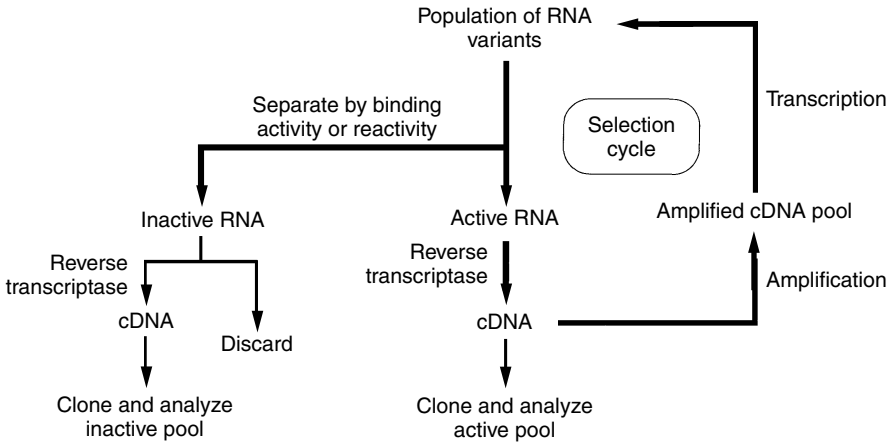

Fig. 7 *In vitro* selection of RNA molecules from a pool of variants. A population of RNA sequence variants is separated into active and inactive molecules on the basis of binding or catalytic activity. Active molecules are copied with reverse transcripts to generate double-stranded cDNA. The cDNA is then amplified, usually through use of the polymerase chain reaction (PCR), making a large pool of the subset of selected sequences. This pool can then be sampled and cloned for analysis or transcribed into a new ''generation'' of RNA molecules and subjected to further rounds of selection.

the few ''active'' molecules that succeed to be in some way separated from the large number that fail. For instance, an RNA molecule that ligates, or joints itself to another RNA, can be separated from inactive molecules by gel electrophoresis because it is now larger than the inactive molecules.

Once the few active RNA molecules have been selected, they can be copied into DNA by the enzyme reverse transcriptase. This complementary DNA (cDNA) can then be amplified manyfold using the polymerase chain reaction (PCR). The amplified cDNA can be used to generate RNA by transcription. Thus, the RNA can be selected for a desired characteristic and then replicated, just as in a genetic selection procedure.

The pool of amplified cDNA sequences can be sampled, cloned, and analyzed to determine the sequences of active molecules. It can also be transcribed to produce a new ''generation'' of RNAs. These molecules can then be sent through the selection procedure again, enriching even more for active RNA sequences (Fig. 7). Multiple rounds of this *in vitro* selection can result in RNA populations containing only a few sequences best capable of catalyzing the desired reaction. This approach has been used to generate novel engineered ribozymes capable of catalyzing many different biochemical reactions not known to be carried out by RNA in modern biological systems.

Keywords

Dicer
An RNase III enzyme responsible for processing siRNAs from long dsRNA, as well as processing mature miRNAs from pre-miRNA hairpins.

microRNAs (miRNA)
Short single strand RNA species that are ~22 nucleotides long and that are encoded by an endogenous class of genes. miRNAs guide the microribonucleoprotein complex (miRNP) to the 3′ untranslated region (UTR) of mRNAs and base pair with imperfect complementarity, resulting in translational repression.

miRNP
Microribonucleoprotein complex; the complex that contains endogenous miRNAs. The miRNP is not as well defined as RISC, either in terms of its protein components or its relevant biochemical activities.

RISC
RNA-induced silencing complex; the complex that contains a single strand of an siRNA, used as a guide to find target mRNAs. RISC catalyzes the cleavage of mRNAs complementary to one strand of the siRNA, resulting in degradation of the mRNA. A main component of RISC in all species is a member of the Argonaute family of proteins.

Short Interfering RNA (siRNA)
An intermediate in the RNAi pathway, processed by Dicer from long double-strand RNA (dsRNA). siRNAs are composed of two ~21 nucleotide RNA strands that are duplexed: there is a region of 19 nucleotide duplex RNA with recessed and phosphorylated 5′ ends and two unpaired nucleotides at the 3′ ends. One strand of the siRNA is incorporated into RISC, guiding it to mRNAs with perfect or near-perfect complementarity, resulting in cleavage of the mRNA.

A revolution has recently swept through biology called *RNA interference*. RNAi serves as an umbrella term, encompassing several phenomena discovered in a diversity of eukaryotes, all of which are mediated by short RNA species. RNAi has been implicated in regulating gene expression by several mechanisms, from transcriptional silencing to mRNA degradation and translational repression. The central role of RNAi processes in gene expression is underscored by its strong conservation across almost all eukaryotes, from plants to fungi to mammals. This review will focus on the discovery of the classical RNAi pathway before considering the molecular details of this pathway. RNAi will then be viewed from a broader perspective, by examining other small RNA directed pathways in a variety of organisms. One pathway in particular will receive ample attention, that of the endogenous microRNA genes, a class of small RNAs that has arisen in multicellular plants and animals. Finally, the adoption of RNAi as a powerful technology will be discussed, including prospects for RNAi-based therapeutic applications.

1 Discovery of RNAi

Of the many remarkable aspects of RNA interference, perhaps the most striking from a historical perspective is that this phenomenon, central to the regulation of gene expression in a wide variety of eukaryotes, evaded the detection of scientists for so long. The initial characterization of this process by Andrew Fire, Craig Mello, and colleagues brought together disparate, and largely unexplained, observations from several model systems and in doing so unlocked an entire field of research that continues to grow at an astounding pace.

As biology marched into the genomic age in the middle of the 1990s, researchers were in the position of having the DNA sequence of genes but no clue as to how these genes might function. Classical genetics (also known as *reverse genetics*) relied on first having a mutant and then working back to find which of the many genes in the genome caused the mutant phenotype. The utility of the approach was beyond doubt, but now, with so much DNA sequence available and more on the way, forward genetic techniques were needed; biologists wanted to start with the DNA sequence of a gene, functionally impair the gene, and then observe the phenotype.

One conceptually simple solution to this problem was antisense technology. This approach attempted to stop gene expression after the DNA had been transcribed into mRNA, but before it was translated into the language of proteins. A researcher would make a nucleic acid with a sequence antisense to the gene of interest, thereby allowing it to base pair with the cognate mRNA. It was assumed that this now double-stranded mRNA would not be competent for translation and the gene would be functionally knocked out. Early experiments in *Caenorhabditis elegans* showed that *in vitro* transcribed antisense RNA, when injected into the worm, would mimic the phenotype of a true genetic knockout. There was a major caveat, however, that was left unexplained

at that time: sense RNA, used as a control because it could not base pair to the mRNA, oftentimes gave the same result!

Fire and Mello had two key insights. First, they noticed that this antisense technique resulted in systemic silencing of the knocked out gene. Even though the worm was injected with the antisense (or sense) RNA in a discreet location, the gene would be silenced essentially throughout the organism. Also, this silencing effect was heritable over several generations. These observations led them to hypothesize that these effects were not a simple antisense effect, which would in all likelihood be local and short lived, but instead that the injected RNA was triggering an endogenous biological response. The second insight was the (educated) guess that the molecular trigger for this process was actually a low level of double-strand RNA (dsRNA) made during the *in vitro* transcription. Fire and Mello reasoned that the RNA polymerase sometimes transcribed the wrong (i.e. sense) strand of the DNA template, and thus the RNA preparations were contaminated with low levels of dsRNA. Experimental proof of this beautifully simple idea was quickly obtained. Annealing sense and antisense RNA before injection resulted in an incredibly potent silencing, and the term *RNA interference* was coined to describe this phenomenon.

RNAi is an evolutionarily ancient process that has been found in all multicellular eukaryotes that have been investigated to date. Versions of RNAi also appear in many single-celled eukaryotes including *Trypanosoma brucei*, *Tetrahymena thermophila*, and the fission yeast *Schizosaccharomyces pombe* (interestingly, there is no evidence for RNAi in the budding yeast *Saccharomyces cerevisiae*). This article focuses on the metazoan RNAi pathway, as defined largely by work done in worm, fly, and mammalian systems, although results from other organisms are discussed when appropriate. Furthermore, RNAi is closely related to a body of research on endogenous small RNAs known as microRNAs (miRNAs), and the biology, implications, and horizons of this field also receive attention. Lastly, while RNAi is a burgeoning field of biology in its own right, RNAi has also become an essential technology. This review covers both the use of RNAi in molecular biology as well as its potential applications in human health.

2 Mechanisms and Components of RNAi

Canonical RNAi (see Fig. 1a) begins when long dsRNA enters the cytoplasm of a cell, where it is processed by the enzyme called *Dicer*. Dicer successively cleaves the dsRNA into smaller fragments known as *short interfering RNA*s (siRNAs). The siRNA is unwound and one of the two strands is incorporated into a multi-subunit protein complex known as the *RNA-induced silencing complex* (RISC). RISC then uses the siRNA as a guide to find and then cleave complementary mRNAs. This section discusses the discovery of these major protein and RNA species and provides further insight into the mechanism of RNAi.

2.1 Dicer

As soon as it was appreciated, in both animal and plant systems, that the long dsRNA which triggered RNAi was processed into siRNAs, the hunt was on for protein responsible for this step. Two characteristics of the siRNA product, the 5′ phosphate and the two unpaired

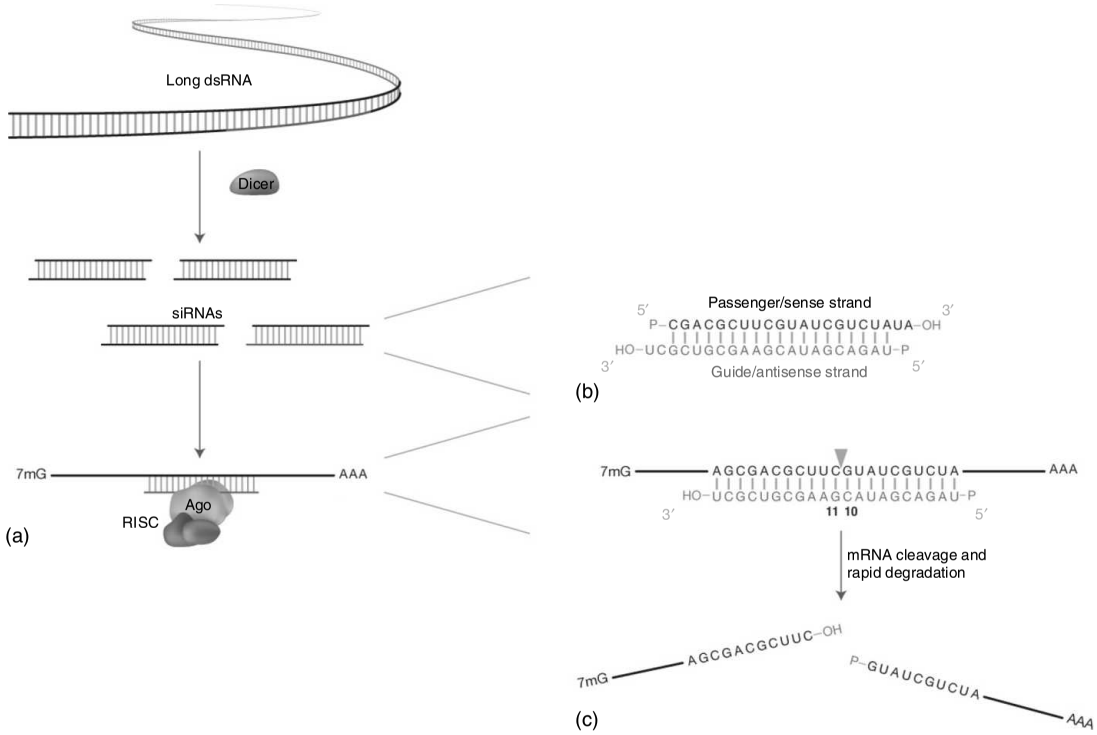

Fig. 1 The RNAi pathway (a) Long dsRNA in the cytoplasm of a cell encounters the enzyme Dicer, which processes the long dsRNA into siRNAs. These siRNAs are unwound and one strand is incorporated into RISC. This guide strand of the siRNA allows RISC to identify target mRNAs and then cleave them, resulting in their degradation. (b) Strand selection of an siRNA. In this example, the strand that will be incorporated into RISC is shown in red, and is designated the guide or antisense strand. This strand is chosen because the first four nucleotides, counting from the 5′ end of the antisense strand of the siRNA, have less thermal stability (A–U rich) than the other strand, which is G–C rich in its first four nucleotides. A helicase activity unwinds this duplex, and hands off one strand to RISC. (c) Target cleavage. The site of the RISC-mediated cleavage is very precise, cleaving between the nucleotides opposite the 10th and 11th bases of the siRNA, counting from the 5′ end of the antisense strand of the siRNA. The RNase H-like cleavage leaves a free hydroxyl on the 5′ region (i.e. the capped end) of the mRNA, and a phosphate on the 3′ half (i.e. the polyadenylated end) (see color plate p. lii).

nucleotides at the 3′ end (see Fig. 1b), suggested that an RNase III enzyme would likely be responsible. A candidate gene approach was undertaken to identify the responsible enzyme, and a bioinformatic search for proteins with a dsRNA binding domain and an RNaseIII domain resulted in a very manageable number of candidates. Affinity-tagged versions of these proteins were expressed and purified. Researchers assayed for the ability to process radiolabeled dsRNA into siRNAs. One of the tagged proteins had this activity, and was named *Dicer*. To confirm this observation, researchers performed an "RNAi–on–RNAi" experiment, to knockdown the expression of Dicer, and thus RNAi activity, via RNAi, with dsRNA homologous to Dicer. While such an approach could not logically be expected to generate a full knockdown of Dicer activity, the attenuation of RNAi activity could still be readily detected, thus proving that Dicer is an essential protein in the RNAi pathway.

A Dicer protein has been found in all organisms that perform RNAi or RNAi-like phenomena. The genomes of *S. Pombe*, *C. elegans*, and mammals reveal only a single Dicer homolog, while Drosophila has two Dicers and *Arabidopsis* has at least four. As might be expected in the latter cases, different Dicers appear to have evolved specialized functions. For example, in Drosophila, Dicer-2 appears to function predominantly in the RNAi pathway, while Dicer-1 is utilized in miRNA biogenesis (see Sect. 4.3). Knockout models reveal that Dicer is essential: in *C. elegans*, homozygous null alleles of Dicer are sterile and survive to adulthood only because of maternal rescue, while a Dicer knockout mouse dies during early embryonic development.

Dicer is necessary and sufficient to cleave long dsRNA into siRNAs, although Dicer interacts with several other proteins *in vivo*. On a molecular level, the best-studied Dicer is mammalian Dicer, which has two RNaseIII domains and a single dsRNA binding motif (dsRBM), as well as a PAZ domain (see Fig. 2). Site-directed mutagenesis studies have made clear the role of each of these domains in the process of siRNA formation. The PAZ domain binds at the free end of the dsRNA, and crystal structures have revealed that the PAZ domain recognizes the two-nucleotide overhang of siRNA-like molecules. Certainly, this domain is also important for recognition during miRNA processing (see Sect. 4.3). Dicer is capable of processing blunt-ended dsRNA, albeit at a decreased efficiency, as would be the case when exogenous dsRNA is used to trigger RNAi (after the first cleavage of a long dsRNA, Dicer leaves a two-nucleotide overhang, thus making subsequent cleavage events more favorable). Binding of the PAZ domain to the end of the dsRNA positions the two RNaseIII domains ~21 nucleotides upstream of the end, with one on each strand of the dsRNA. Using conserved aspartic acid and glutamic acid residues, each RNaseIII domain then makes a single cut in its substrate strand, resulting in the liberation of an siRNA.

2.2 siRNAs

Initial biochemical study of the RNAi pathway was performed in Drosophila embryo lysates. After establishing that dsRNA would lead to destruction of target mRNA in this *in vitro* system, researchers asked what happened to the trigger dsRNA. By labeling their input dsRNA, incubating

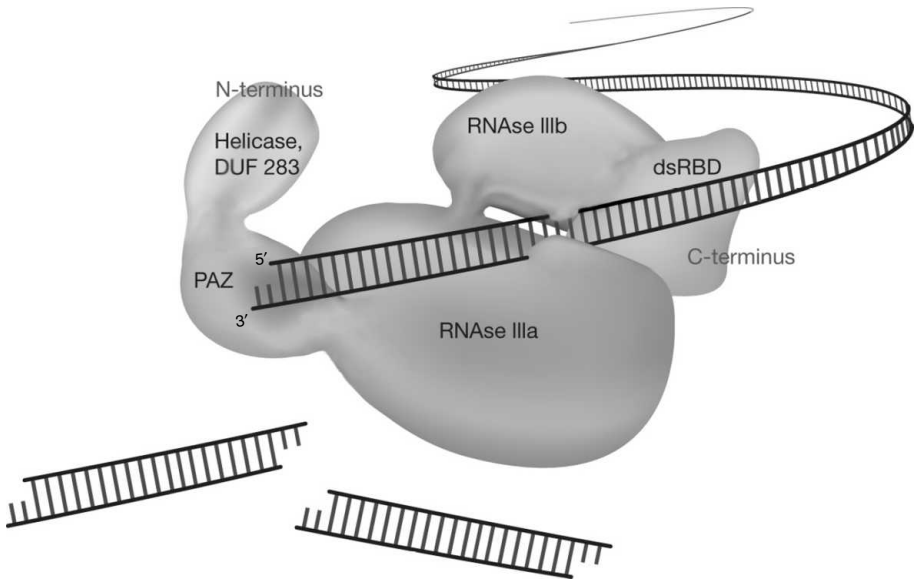

Fig. 2 Recognition and cleavage of dsRNA substrates by Dicer. This schematic illustrates how the different domains of Dicer bind to a dsRNA substrate. The PAZ domain recognizes the two unpaired nucleotides at the 3′ end resulting from a previous Dicer cleavage, in the case of RNAi, or from Drosha cleavage, in the case of miRNA processing. The two RNaseIII domains are then positioned ~21 nucleotides away from the base, and each cleaves one strand of the RNA. From Zhang, H., Kolb, F.A., Jaskiewicz, L., Westhof, E., Filipowicz, W. (2004) Single processing center models for human Dicer and bacterial RNase III, *Cell* **118**, 57–68.

it in the lysate, and then running the products on a polyacrylamide gel, they observed that the long, input dsRNA was processed into a smaller RNA species, of ~21 nucleotides in length (see Fig. 3). This short RNA species was then cut out of the gel to see if it alone could potentiate the degradation of target mRNA, and indeed it could, meaning that this RNA is a true intermediate in the pathway. Chemical characterization revealed that these 21 nucleotide species are double stranded and each strand has a 5′ phosphate. While each strand is 21 nucleotides, the strands are duplexed in a staggered manner, with 19 nucleotides of duplex and two unpaired nucleotides at the 3′ end. This species was originally named short interfering RNA or siRNA, although the literature quickly began interchanging ''short'' and ''small.''

2.3 Asymmetry of siRNAs

A question often posed to RNAi researchers by scientists outside the field attempting to use the technology of RNAi was ''why doesn't my siRNA work?'' Initially, the only hard and fast rule about siRNAs was that they worked, except when they did not. A great deal of unsuccessful siRNA-based experiments were explained when one lab hit upon the hypothesis that perhaps nonfunctional siRNAs were nonfunctional because the wrong strand of the siRNA was being incorporated into RISC. In other words, when researchers design

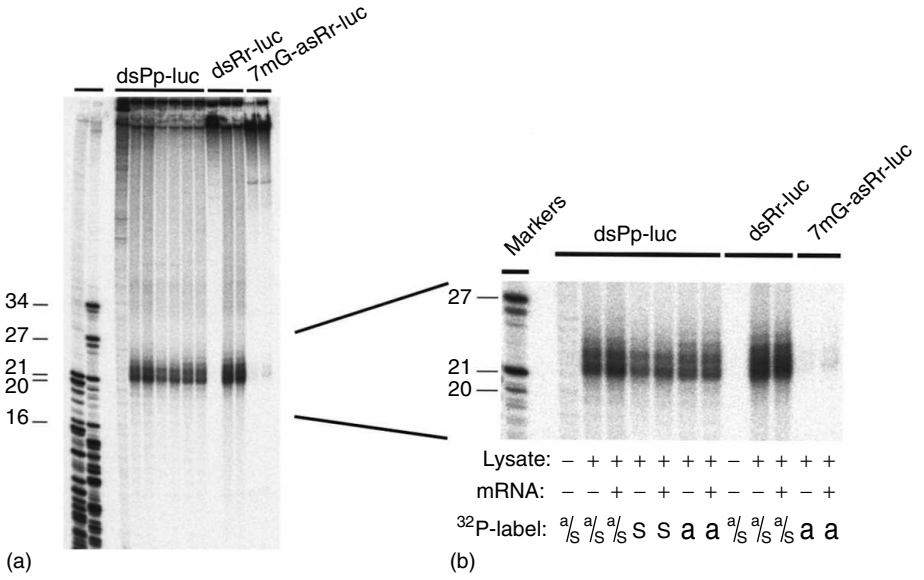

Fig. 3 Identification of siRNAs as intermediates in the RNAi pathway. Radiolabeled dsRNA was incubated in a Drosophila embryo lysate, and the subsequent polyacrylamide gel showed the appearance of a small RNA species. Two different dsRNAs were used, dsPp-luc and dsRr-luc, showing that this was not specific to a given dsRNA sequence. Furthermore, single-stranded RNA (7 mG-asRr-luc) did not yield small RNA species. Part B, a zoom-in of part A, shows that these species are in fact double strand, as either strand of the input dsRNA could be labeled and give rise to the small RNA. The small RNA species appears regardless of the presence of a target mRNA. From Zamore, P.D., Tuschl, T., Sharp, P.A., Bartel, D.P. (2000) RNAi: double-stranded RNA directs the ATP-dependent cleavage of mRNA at 21 to 23 nucleotide intervals, *Cell* **101**, 25–33.

siRNAs to target genes of interest, they know which strand of this geometrically symmetric molecule they want to function as the guide strand of RISC, but RISC itself, of course, does not. Phil Zamore and colleagues hypothesized that a helicase activity must unwind the double-strand siRNA and hand off one strand to RISC, and that perhaps the helicase has a preferred end of the molecule from which to unwind.

Examination of siRNAs used in the lab revealed that functional siRNAs tended to have an A or a U as the first nucleotide of the guide strand, while nonfunctional siRNAs tended to start with a G or C. Thermodynamically, an A–U base pair has less stability than a G–C base pair, and thus the A–U base-paired end would be easier for the helicase to unwind. The necessary experiments were performed to confirm this hypothesis, showing that the thermodynamic stability of the first four nucleotides on each side were very predictive of which strand would be incorporated into RISC (see Fig. 1b). These data are supported by experiments analyzing hundreds of functional and nonfunctional siRNAs synthesized by a leading industrial provider of siRNAs. This strand preference should be followed in designing siRNAs, but there are certainly

more criteria, both known and unknown, that further contribute to the functionality of siRNAs.

2.4 RISC

RISC is a multi-subunit complex that carries out the final step in the RNAi pathway, cleavage of the target mRNA. This definition is rather strict, as there are almost certainly many RISC-like complexes in cells that are not exclusively involved in canonical RNAi. For example, miRNAs involved in translational repression associate with a related complex known simply as the *microribonucleoprotein* complex (miRNP) (see Sect. 4.4). Although different organisms and purification schemes have yielded different accessory proteins, one constant is the central role of an Argonaute family member.

2.4.1 The Argonaute Family of Proteins

Argonaute proteins are defined by both a PAZ domain (see Sect. 2.1) and a PIWI domain, which forms an RNase H-like fold. Argonaute proteins are further divided into two subfamilies, the Piwi subfamily and the Ago subfamily. Members of the Piwi subfamily play a role in silencing phenomena. For example, the Drosophila protein piwi is needed for both transcriptional and posttranscriptional gene silencing (see Sect. 3.4). The Ago subfamily has been directly implicated in canonical RNAi. In Drosophila, Ago-2 was quickly identified as a core component of RISC, and biochemical purification from human cells confirmed that human Ago-2 (originally named *eIF2c2*) is the main component responsible for siRNA-directed mRNA cleavage. Interestingly, the human genome has four well-defined Ago proteins, and all four bind to siRNAs and miRNAs, yet only Ago-2 is capable of cleaving mRNA targets. Certainly, some if not all of the Ago proteins are involved in the miRNA pathway, and it will be interesting to see what different roles the Ago proteins play in small RNA silencing pathways. Although Argonaute proteins are core components of RISC, they appear to work at many steps in the RNAi pathway. One of the original RNAi deficient worms, *rde-1*, encodes for an Argonaute protein that works upstream of the generation of siRNAs, while two other Argonaute proteins in worms, *alg-1* and *alg-2*, are important for miRNA biogenesis.

2.4.2 Target Selection and Cleavage

The details of siRNA-directed mRNA cleavage have been established in two biochemically tractable systems, mammalian and Drosophila extracts. Experiments have shown that the siRNA guides RISC to the mRNA and cleaves the mRNA between the bases opposite bases 10 and 11 of the siRNA, counting from the 5′ end. This cleavage leaves a 3′ hydroxyl on the 5′ end of the cleaved mRNA and a 5′ phosphate on the 3′ end (see Fig. 1c). *In vitro* analysis of this reaction demonstrated that this cleavage is catalytic and conforms to Michaelis–Menten kinetics, as a single RISC molecule can cleave multiple mRNAs.

As might be inferred from the cleavage products, RISC does not mediate cleavage via the mechanisms employed by common RNases such as RNase A, which produce a 5′ hydroxyl and a 2′3′ cyclic phosphate. For quite some time, researchers pursued the elusive "Slicer" protein that catalyzed the mRNA cleavage, but the crystal structure of an Argonaute protein revealed that Ago itself is responsible for the cleavage. The PIWI domain of Ago adopts an RNase H fold, an observation that is consistent

with the known cleavage products of RISC. As mentioned, only mammalian Ago-2 is capable of catalyzing mRNA cleavage, yet the other three mammalian Ago family members have a conserved PIWI domain with the appropriate residues at the catalytic center of the enzyme. Ago-1, 3, and 4, however, have mutated glutamine and histidine residues outside the proposed active site that eliminate the ability of these three Ago proteins to cleave mRNA. It is not clear at this point how these two mutations disrupt the cleavage activity, but it has been proposed that these two residues coordinate metal ions needed for catalysis.

2.4.3 Off-target Effects of siRNAs

For RNAi to be useful to an organism, the signal that it generates must be specific for the intended RNA. Likewise, specificity is an important parameter for RNAi to be a successful tool, to ensure that any observations are due to knockdown of the gene of interest rather than other genes. Biochemical studies in various *in vitro* systems have shown that the guide strand of the siRNA does not need to base pair throughout the target, but that more-limited complementarity can produce mRNA cleavage, albeit at a greatly reduced rate. Importantly, it is not clear if this limited cleavage has a phenotypic effect in live cells or whole organisms. To assess the effects of siRNAs in a genome-wide context, extensive microarray analyses have been performed. These results show that, on average, a given siRNA will modestly downregulate approximately 50 unintended genes. Most of the genes downregulated do in fact have some stretches of complementarity to the siRNA, especially in the 5′ region, and thus are likely to be cleaved via an RNAi-like mechanism.

This problem of less-than-perfect specificity has been addressed in several ways. First, one potential source of off-target effects is the entry of the wrong strand of the siRNA into RISC. With a better understanding of siRNA asymmetry (see Sect. 2.3), this problem can now be avoided. Second, siRNAs of different sequence can be used to confirm that a phenotype is due to knockdown of the gene of interest rather than an off-target effect; because the siRNAs have different sequence, the off-target profile would be different. It is also important to bear in mind that RNAi is a natural process, and that evolution has selected for its presence. Therefore, the usefulness of RNAi to the host organisms throughout evolution strongly outweighed the potentially detrimental effects of silencing unintended genes.

2.5 RNA-dependent RNA Polymerases

A significant difference between RNAi in plants, worms, and fungi from that in flies and mammals is the requirement for an RNA-dependent RNA polymerase (RdRP) activity in the former. RdRPs amplify the RNAi signal, and RdRP proteins are required for productive RNAi in organisms that have them. siRNAs generated from Dicer cleavage can go down either of two paths. First, the guide strand of the siRNA can enter RISC and perform mRNA target cleavage. Alternatively, the guide strand of an siRNA can function as a primer, binding to the mRNA target and allowing polymerization of an RNA strand antisense to the mRNA. This now-dsRNA can serve as a substrate for Dicer, producing a second generation of siRNAs, thereby amplifying the RNAi effect.

RdRP activity was formally proven to be a part of the RNAi pathway in an experiment in *C. elegans* utilizing a *pha-4*:GFP fusion transgene, such that the mRNA would code for *pha-4* in its 5′ half and GFP in its 3′ half. As expected, dsRNA homologous only to GFP silenced this transgene. This same dsRNA also silenced endogenous *pha-4*, implying that siRNAs generated against the GFP were then extended by an RdRP activity to make dsRNA homologous to *pha-4*. These siRNAs could now target the endogenously encoded *pha-4* mRNAs, thus silencing *pha-4* in trans and leading to the term *transitive RNAi*. Importantly, if the experiment were reversed and *pha-4* were the 3′ half of the fused transgene, dsRNA against GFP would not cause silencing of endogenous *pha-4*, implying a directionality to the RdRP activity.

Bioinformatics has shown that no RdRP homologs exist in either the mammalian or Drosophila genomes. Biochemical analysis has shown that siRNAs with modifications on their 3′ ends, such that the 3′ end could not serve as a primer for extending an RNA transcript, were still able to support RNAi. Thus, it can be concluded that RdRP is not necessary for robust RNAi in these organisms. Why this RdRP activity was apparently lost during insect and vertebrate development is unclear.

3 Endogenous Roles for RNAi

While one can never know for sure the selective pressures guiding evolution, it is unlikely that RNAi evolved as a means for researchers to knockout their favorite genes. As work in plants and *C. elegans* has made clear, RNAi serves as a defense mechanism against invading genetic elements. Furthermore, the RNAi machinery is used not only as an immediate posttranscriptional response, but also silences genes for the long term, on the transcriptional level.

3.1 Cosuppression

In plant systems, it had been known for some time that transgenes introduced into plants with the purpose of overexpressing a gene would, sometimes, actually produce a knockdown of both the transgene and any endogenous copies (see Fig. 4a). Initially termed *cosuppression*, a clear mechanistic understanding of this process was lacking. A Northern blot provided a key piece of data, showing the appearance of 20 to 25 nucleotide RNAs homologous to the now-silenced gene, while these species were absent in the plants that were not suppressing gene expression (see Fig. 4b). This seminal observation made clear that an RNAi-like process was occurring in cosuppression. Cosuppression is also observed in *C. elegans*, Drosophila, and Neurospora (where it is termed *quelling*) and in all cases, RNAi proteins and small RNAs have been implicated in the process.

3.2 Silencing of Invading Genetic Elements

The genomes of higher organisms are littered with potentially deleterious genetic elements, such as transposons, LINEs, and SINEs, and RNAi serves as a defense mechanism to keep them in check. Early screens for worms defective in the RNAi pathway showed a connection between RNAi and transposon silencing, as some worms that had already been identified as mutant for silencing transposons (designated as *mut* for mutator, as the decreased ability to silence transposons resulted in

heightened mutation frequency in these worms) were also deficient in RNAi. Likewise, some of the worms identified in a screen for RNAi deficiency (*rde* mutants) also showed mutator phenotypes. An interesting example of RNAi used to regulate an endogenous gene occurs in Drosophila, where the *Stellate* locus needs to be silenced in order for proper meiosis. A locus known to suppress *Stellate*, Su(Ste), is actually a series of repeats that triggers the RNAi pathway by producing both sense and antisense RNA, which are homologous to *Stellate* and silence it via the RNAi pathway. An Argonaute family member, *aubergine*, is required for this silencing as is *Spindle-E*, an RNA helicase.

In plants, it was quickly appreciated that RNAi constituted an immune system against viruses. When a plant is infected with a virus, it uses the RNAi machinery first to silence the virus in the infected cells. Plants also mount a second response, sending a signal to other cells of the plant, a phenomenon known as *spreading*. This signal renders those other cells immune to a second attack by the same virus. As would be expected in the evolutionary arms race between pathogen and host, some viruses have evolved mechanisms to defend against the endogenous RNAi response. For example, tombusvirus encodes the P19 protein that binds tightly to siRNAs, thus titrating them out of the cell and allowing viral replication.

3.3 Transcriptional Silencing

RNAi was first recognized as a posttranscriptional phenomenon, but even from the beginning, there were many tantalizing hints of a transcriptional arm of the general term that is RNAi, both via DNA and histone modifications. The results were most clear in the plant field. Researchers showed that a plant would trigger canonical RNAi if dsRNA homologous to the coding sequence of a gene was introduced. dsRNA designed against the promoter region of a gene, however, also resulted in silencing of the gene. Since the dsRNA was not homologous to an expressed RNA, something distinct from RNAi was occurring. Further experimentation showed that the DNA homologous to the dsRNA is methylated, a common way for many organisms to silence gene expression at the level of transcription. Further research has

Fig. 4 Cosuppression in plants. (a) Initial observation of cosuppression phenomena. The parental strain of petunia is purple due to the expression of endogenous chalcone synthase. When transgenic lines were made to express more chalcone synthase, many of the plants did not become more purple as would be expected, but in fact lost chalcone synthase expression, resulting in a white color. From Napoli, C., Lemieux, C., Jorgensen, R. (1990). Introduction of a chimeric chalcone synthase gene into petunia results in reversible cosuppression of homologous genes in trans. *Plant Cell* **2**, 279–289.(b) Cosuppression and disappearance of mRNA correlates with appearance of small RNAs. In a similar situation as that shown in 4a, a transgene with the 1-aminocyclopropane-1-carboxylate oxidase (ACO) gene, an endogenous tomato gene, was transformed into tomatoes. Part A is a Northern blot for the ACO mRNA, and 3 of the 5 transgenic plants still express ACO, while two have now silenced ACO. Part B shows the appearance of small RNAs antisense to ACO appearing in the silenced strains but not the ACO-expressing strains. Part C shows that these small RNA species are double stranded, as they also hybridize to the antisense transcript of ACO. From Hamilton, A.J., Baulcombe, D.C. (1999) A species of small antisense RNA in posttranscriptional gene silencing in plants, *Science* **286**, 950–952.

indicated that the RNAi pathway can also alter chromatin structure in plants, leading to the methylation of histone 3 lysine 9 (H3K9) and thus the condensation and silencing of those regions of DNA.

The fission yeast *S. pombe* has one homolog each of three RNAi proteins: Dicer, Argonaute, and RdRP. Knockout strains of each individual protein revealed the same phenotype, a defect in centromere definition due to inappropriate transcription. In this organism, the RNAi machinery generates a small RNA species that is used to guide the RITS complex (RNA-induced initiation of transcriptional gene silencing) to modify chromatin structure. RITS recruits the histone methyltransferase Clr4 to methylate H3K9, which then recruits Swi6, the yeast ortholog of metazoan HP1. This type of silencing appears important in defining both the centromeric region and the mating-type locus.

Plants, flies, and budding yeast have provided the three best-characterized examples of transcriptional silencing directed by short RNAs to date, but new research continues to point to transcriptional silencing in other organisms as well. For example, researchers have shown that siRNAs transfected into mammalian cells targeted against promoter sequences can indeed induce transcriptional silencing. While this observation has not yet been tied to an endogenous process, the role of methylation in mammalian biology is well established, and it is tempting to speculate that small RNAs play a role in providing specificity to transcriptional silencing phenomena.

3.4 Generation of the Silencing Signal

Given that a dsRNA trigger is needed to provoke RNAi, a key question centers on how dsRNA forms from an endogenous source to provoke any of the phenomena discussed earlier. One possible model hypothesizes that the transcripts arising from these loci are somehow aberrant, and thus recognized by RdRPs and converted into dsRNA. This explanation is unsatisfyingly vague and cannot account for organisms that do not have an RdRP in their genome. Perhaps, an increase in the copy number of a gene increases the chance of read-through transcription from another locus, thereby potentially leading to antisense transcripts that could form dsRNA. This hypothesis has experimental support, as increasing the copy number of a transgene was shown to provoke both transcriptional and posttranscriptional silencing in Drosophila in a manner dependent on the Argonaute protein piwi. Many of the repetitive elements in the human genome are remnants of retroviruses that contain promoters in their long terminal repeats (LTRs). Indeed, it has recently been appreciated that there is a great deal of antisense transcription in the genome, perhaps serving as a means of quality control, whereby the wrong proportion of sense and antisense would lead to dsRNA formation and thus trigger RNAi.

4 MicroRNAs

It was not long after the discovery of siRNAs in the original Drosophila lysate experiments that an obvious question arose: are there endogenous siRNAs? These experiments led to the discovery of a large class of endogenously encoded small RNAs that were termed *microRNAs* or miRNAs. miRNAs have the interesting distinction of essentially being discovered twice, as work in worms had previously identified a small RNA that remained an

isolated observation for some time. The *lin-4* RNA would turn out, however, to be the founding member of a large class of very interesting genes.

4.1 Dual Discovery of a Large Class of Genes

The cloning approaches used to look for siRNAs selected for these species by two key properties. First, siRNAs are a defined size, so one step of cloning involves size fractionation of RNA on a denaturing polyacrylamide gel, to isolate RNAs of approximately 21 nucleotides. Of course, by running a denaturing gel, any siRNAs in the population are separated into the sense and antisense strands. Second, siRNAs contain a 5′ phosphate and a 3′ hydroxyl group, whereas most RNA degradation products do not. To take advantage of this property, a linker is ligated onto the 3′ end of the RNA population, in an ATP-independent reaction to prevent circularization of the small RNA molecules. A second linker is ligated onto the 5′ end, in a manner dependent on the presence of a 5′ phosphate. The resulting product is amplified by reverse transcription and polymerase chain reaction, then cloned into bacteria and sequenced.

The results of initial cloning experiments were not, as expected, large numbers of RNA sequences that could form perfect complements with two-nucleotide overhangs with other RNA sequences in the population, that is, endogenous siRNAs. Instead, the researchers found sequences that appeared to exist predominately as single-stranded RNA in the cell. Interestingly, when these RNA sequences were found in their genomic context, the transcript that would contain these sequences would invariably form a hairpin structure. Northern blots for these species showed not only the single-stranded ~22 nucleotide form that was cloned but also a band at ~60–70 nucleotides, corresponding to the hairpin structure. As further evidence that these cloned products were "real" and not simply random degradation products, several of the sequences were conserved from worms to flies to mammals. The first cloning efforts yielded several dozen of these small RNA species in each organism, and this new class of RNA species was dubbed microRNAs.

Concurrent with these cloning efforts, researchers in the RNAi field began to appreciate some previous work on very interesting small, endogenous RNAs. In the early 1980s, a screen was performed in *C. elegans* for genes involved in lineage defects (*lin* mutants). During the late 1980s and up through the 1990s, one of these mutants became a decade-long research effort spearheaded by Gary Ruvkun and Victor Ambros. The *lin-4* mutant showed an interesting phenotype, whereby certain cells were retarded, meaning that instead of differentiating during the life of the worm, they continually divided into the same cell type. Another mutant, the *lin-14* mutant, showed the opposite phenotype; a precocious mutant, it skipped over early developmental stages. It was determined that the cause of the *lin-14* mutant phenotype was not a mutation in the coding sequence of the protein, but rather in the 3′ untranslated region (UTR) of the mRNA. Owing to their opposite phenotypes, it was hypothesized that the *lin-4* gene product regulated *lin-14*. Mapping of the *lin-4* mutation was incredibly laborious, and the *lin-4* locus became winnowed down to a smaller and smaller region, making it less and less likely that *lin-4* could encode a protein. Finally, it was determined that *lin-4* did not code for a protein but rather for a

small RNA species. Furthermore, when the sequence of the ~22 nucleotide *lin-4* RNA was determined, it was immediately noticed that it shared a great deal of complementarity to several regulatory regions in the *lin-14* 3′ UTR. Further experimentation proved the importance of this RNA:RNA interaction, and *lin-4* was called a *small temporal RNA* (stRNA) for its important role in proper developmental timing.

For almost a decade, *lin-4* remained an isolated case, a strange ''worm-thing.'' In the late 1990s, however, when RNAi was discovered, this ''other'' small RNA started to receive more notice, and researchers also found another example in the worm of a small RNA gene controlling development, *let-7*. To complete the connection to RNAi, genetic, and biochemical studies implicated Dicer in processing the hairpin precursor to the ~22 nucleotide mature RNA, and several Argonaute proteins were also needed for their biogenesis and function. Not surprisingly, cloning efforts from *C. elegans* for siRNAs identified both *let-7* and *lin-4*, and thus *lin-4* became the founding member of this very exciting new class of genes, the microRNAs.

Initial efforts resulted in a few dozen miRNAs identified in worms, flies, and humans, and the original results are revealing. Some miRNAs are highly conserved across evolution, while other are specific to a given species. Furthermore, within a species, it is clear that some miRNAs are related, as they have similar sequences, especially in the 5′ region of the miRNA. Like *lin-4*, many miRNAs have unique expression patterns, appearing at certain times in development or in certain tissues. As cloning efforts have expanded and computational methods are used to predict miRNAs, more miRNAs have been discovered, and there appear to be 200 to 1000 miRNAs in the human genome. Given that there are 25 000 to 30 000 genes in the human genome, miRNAs are indeed a large class of genes.

4.2 Mechanism of miRNAs

Almost all that is known about the function of miRNAs comes from studies performed on the *lin-4*:*lin-14* interaction. The *lin-4*-mediated repression of *lin-14*, unlike RNAi, does not occur via targeting the *lin-14* mRNA for cleavage and degradation. Northern blot analysis shows that *lin-14* levels remain the same when *lin-4* expression increases during the L1 to L2 developmental transition. There are central bulges in all of the several *lin-4*:*lin-14* interactions, and RNAi requires essentially perfect duplexes for full cleavage activity. Because mRNA levels do not appear to be changed, this is not a posttranscriptional phenomenon like RNAi, but instead has been dubbed ''translational repression.'' It is possible that *lin-4* does not affect the process of translation *per se*, but instead destabilizes the newly made protein; nevertheless, this type of repression is currently known as *translational repression*.

Biochemical analysis of the *lin-4*:*lin-14* interaction revealed that *lin-4* does not cause *lin-14* to lose ribosomes, as the mRNA remains in the polysome fraction of a sucrose gradient. This result is interpreted as indicating that translation initiates properly on the repressed mRNA; otherwise, the *lin-14* mRNA would be associated with fewer ribosomes, and thus would fractionate differently. This same result has been seen with the *lin-28* mRNA, another target of *lin-4*. These are but two studies, and both were performed in *C. elegans*. Future work in this system and in other organisms will be needed to gain

a deeper understanding of how miRNAs actually lead to a decrease in steady state protein levels. Indeed, an immediate alternative to this pathway is found in plants. Plant miRNAs, unlike metazoan miRNAs, oftentimes have extensive complementarity to known mRNAs, and function in an RNAi-like fashion, cleaving the target mRNA. And while most animal miRNAs have limited complementarity to any mRNA, miR-196 bears almost exact complementarity to the *HOXB8* gene, which appears to be cleaved in an RNAi-like fashion. Clearly, the world of miRNAs and siRNAs are overlapping (see Sect. 4.4).

4.3 Biogenesis of miRNAs

MicroRNAs are found in diverse locations in the genome (see Fig. 5). Some are entirely on their own, whereas others are grouped in clusters, probably to allow coordinate expression. Some miRNAs are found far away from any known protein-coding genes, while a good number (~25% in humans) are actually found within introns. miRNAs are not expressed as 22 nucleotide transcripts but rather as very long primary transcripts (pri-miRNA), and these appear to be transcribed by RNA polymerase II, the same polymerase that transcribes protein-coding mRNAs. Another RNase III enzyme, Drosha, recognizes the hairpin that contains the miRNA and cuts it out of the primary transcript, to produce a 60 to 70 nucleotide hairpin known as the precursor-miRNA (pre-miRNA). Like Dicer, the Drosha cut generates the telltale 5′ phosphate and two-nucleotide 3′ overhang. This structure is then recognized by Exportin 5, and the pre-miRNA is exported into the cytoplasm.

In the cytoplasm, the pre-miRNA encounters Dicer. In worms and mammals, it appears that the same Dicer is responsible for both RNAi and miRNA processing, but in Drosophila, there are two Dicers, one for each pathway. The PAZ domain of Dicer recognizes the 5′ phosphate and two unpaired nucleotides, and uses this to position the two RNase III domains, one on each strand of the hairpin stem. Dicer then catalyzes two cleavages, to produce a molecule that bears much similarity to a canonical siRNA. However, as mentioned before, miRNAs are found largely as single-stranded species. Correlative evidence suggests that the same rules underlying siRNA strand selection (see Sect. 2.3) apply to miRNAs, and this siRNA-like intermediate is soon unwound, with one strand being stabilized in an miRNP, whereas the other strand is rapidly degraded.

4.4 Proteins Associated with miRNAs: the miRNP

The ribonucleoprotein complex that contains miRNAs, known simply as the miRNP, is not as well-defined biochemically as RISC, largely because what miRNAs do is largely unknown and thus the miRNP does not yet lend itself to biochemical assays (see Sect. 4.2). It is known that the miRNP contains an Argonaute protein, as an antibody against human Ago-2 immunoprecipitates many miRNAs. Furthermore, overexpressed, tagged versions of human Ago-1, 2, 3, and 4 all associate with endogenous miRNAs, although only Ago-2 is capable of using the miRNA to catalyze RNA cleavage (see Sect. 2.4.2). In Drosophila, Ago-1 associates preferentially with miRNAs while Ago-2 associates with siRNAs, although unlike in mammals, both Ago proteins can catalyze mRNA cleavage.

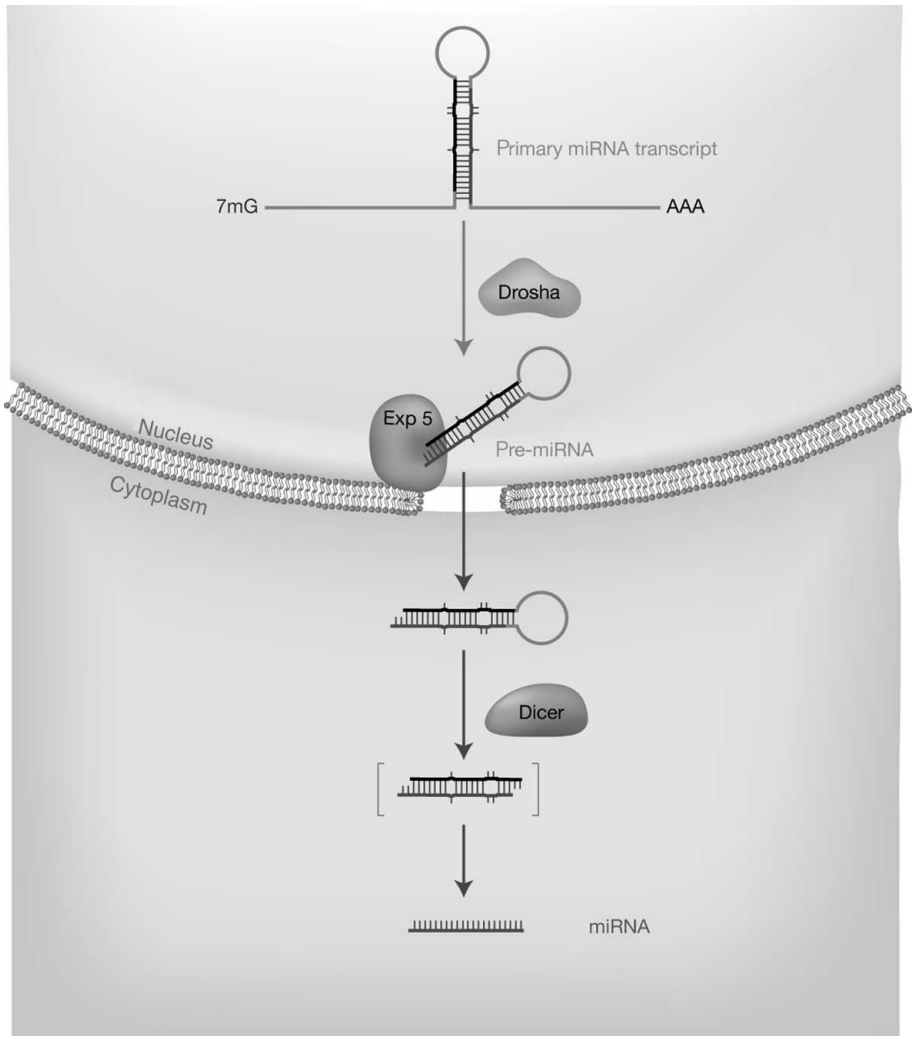

Fig. 5 MicroRNA biogenesis pathway.

In human cells, Gemin 3 and Gemin 4 are found associated with Ago-2 and with miRNAs. Gemin 3, a DEAD-box RNA helicase, and Gemin 4, a novel protein, were previously found associated with the Survival of Motor Neuron (SMN) complex, which is predominantly nuclear and is important for biogenesis of many ribonucleoproteins. SMN is a complex distinct from the miRNP, as several other Gemins associate with SMN that are not found as part of the miRNP; likewise, Ago-2 does not associate with these other Gemins. The association with Ago-2 appears to be a separate function of Gemin 3 and Gemin 4, although their roles are not yet known. Purification of the minimal protein components of RISC activity does not yield Gemin 3 or 4, arguing that they are not necessary for mRNA cleavage

and instead function predominantly in the miRNA pathway.

An important protein in neurobiology has been found associated with Ago-2, the Drosophila homolog of the human Fragile X Mental Retardation Protein (FMRP). Human genetic studies have shown that disruption of this protein leads to one of the most common forms of inherited mental retardation. FMRP is known to associate with mRNAs in neurons, and loss of FMRP alters plasticity at synapses. Identified in a biochemical purification of RISC activity, FMRP is not necessary for mRNA cleavage, and at this point, it is not clear what role FMRP may play in RISC or the miRNP. Many researchers have speculated that FMRP provides additional specificity to miRNA-containing complexes, as FMRP is known to bind to the 3′ UTR of mRNAs and regulate their translation.

4.5 Overlap and Distinctions between RNAi and Translational Repression

Certainly, there is a great deal of overlap between RNAi and translational repression, as target genes are silenced by short RNAs in both cases. However, these silencing pathways are qualitatively different, as the former results in a reduction of mRNA through cleavage, whereas the latter results in stable amounts of mRNA and translational repression occurs by mechanisms that are incompletely understood. The miRNP that contains an miRNA is capable of mRNA cleavage, if the mRNA target has sufficient complementarity. Conversely, exogenous siRNAs are capable of translationally repressing a target mRNA with imperfectly complementary binding sites. Furthermore, Dicer is needed in both pathways for generation of the small RNA that guides the protein complex to the target mRNA.

These pathways are certainly distinct, however. A knockout mouse of Ago-2 is embryonic lethal, but mouse embryonic fibroblasts (MEFs) can be derived. As expected, these MEFs are no longer capable of performing RNAi with a perfectly complementary RNA:RNA interaction, but translational-repression activity is still intact. This result implies that, in mammals, at least one of the other Argonautes (the human genome has four closely related Argonautes) can perform translational repression. The decision between mRNA cleavage and translational repression appears to depend on the extent of complementarity between small RNA and target mRNA, although future work will be needed to see if additional factors also modulate this decision.

4.6 MicroRNAs and their Targets

The discovery of miRNAs as an abundant class of regulatory RNAs immediately prompted investigation into the potential target mRNAs. The first examples of regulation were all found via classical genetic approaches, whereby mutagenesis happened to hit the miRNA (or its binding sites in the 3′ UTR) and thus disrupted its function. In addition to the *C. elegans* examples of *lin-4* regulating *lin-14* and *lin-28*, and *let-7* regulating *lin-41*, several other interactions have been found. For example, the *bantam* locus in Drosophila was simply a mutant locus and there was no clear sense of how this mutation caused the phenotype of premature apoptosis. With the discovery of miRNAs, it was soon appreciated that the *bantam* locus contained an miRNA, and experiments

showed that *bantam* repressed the expression of the proapoptotic gene *hid*. Classical genetic approaches are likely of limited use for finding miRNA targets, however, as an miRNA is a relatively small target for random mutagenesis as compared to a protein-coding gene. Furthermore, evidence suggests that miRNA family members can function redundantly. An alternative approach to this problem is computational biology.

A few general rules have been developed for miRNA:mRNA target interactions, derived both from observations of known targets and from direct experimentation. Of course, these rules are open for revision as more interactions are verified. Furthermore, what follows is a discussion applying to animal miRNAs; plant miRNA targets have been much easier to predict computationally, as they bear significantly more complementarity to their target. These algorithms generally assume that the miRNA targets the 3′ UTR of the mRNA, as is the case for *lin-14*, *lin-28*, *lin-41*, and *hid*. Second, an miRNA will likely bind to the target mRNA multiple times, although coordinate regulation, whereby several different miRNAs bind to a single mRNA, has experimental support, and certainly cannot be discounted. Third, the 5′ region of the miRNA, sometimes referred to as the *seed* region, is a critical determinant of activity, and there is both computational and experimental evidence to support this assumption. Lastly, some computational approaches rely on conservation of a binding site across several species. Certainly this criterion helps eliminate false-positive predictions, but also loses miRNA targets that are specific for a given species.

Several attempts have been made to define miRNA targets in this computational approach, and the results are, perhaps expectedly, quite varied, depending on the exact nature of the algorithm in terms of the relative weight of the different assumptions and parameters discussed earlier. What is clear, however, is that miRNAs have the potential to regulate many genes, a conclusion bolstered by direct experimentation showing that as few as ~8 nucleotides of complementarity between miRNA and target mRNA can give translational-repression activity. Do miRNAs regulate almost every transcript in a cell, fine-tuning the expression of each mRNA, serving as "micromanagers" of gene expression? Or perhaps there are as-yet-unknown specificity determinants, such as protein components of the miRNP that help guide miRNAs to a subset of mRNAs.

5
RNAi as a Technology

The ability to significantly reduce the expression of theoretically any gene, in a wide variety of organisms, has made RNAi a powerful component of the biologists' toolkit. This section will examine how researchers use RNAi as a tool and the promise of RNAi as a potential therapeutic.

5.1
Methods of Triggering RNAi

Depending on the organism under investigation, RNAi is triggered via different means. In *C. elegans,* the first demonstration of RNAi relied on injection of *in vitro* transcribed dsRNA into the worm, a somewhat technically demanding process that does not readily lend itself to high-throughput approaches. Fortunately,

several easier approaches have been developed. One involves a plasmid expressing dsRNA in the bacteria that also serve as the worms' food. When the worm ingests the bacteria, enough of the dsRNA gets into the worm to trigger RNAi. Clearly, this approach does lend itself to high-throughput screens, as a cDNA library can simply be inserted into the plasmid to create an RNAi library. Remarkably, RNAi can also be induced by simply soaking the worm in a solution of dsRNA. Soaking also works in a standard Drosophila-derived S2 cell line, although this approach does not work in mammalian cell lines.

RNAi as a tool has greatly impacted researchers working in mammalian systems. Previously, mammalian biologists had to construct transgenic mice to study the knockout phenotype of a gene of interest, a costly and laborious process. With the advent of RNAi, however, researchers working both in mammalian cell culture systems and in organisms have finally been able to perform reverse genetics. In mammalian systems, the standard way of inducing RNAi is not with long dsRNA, as this molecule would trigger the interferon response, an antiviral mechanism that results in cell death. Instead, siRNAs are used to enter the pathway at an intermediate step, as siRNAs are short enough to avoid the interferon response. These siRNAs are usually chemically synthesized at a relatively inexpensive cost, and are delivered to cells via cationic lipid transfection or electroporation. Maximal gene knockdown on the RNA level occurs within 48 to 72 h after transfection in normally dividing cells, and after that the knockdown effect begins to dilute out as the cell divides.

While siRNA transfection has been widely used, there is certainly an interest in making the RNAi effect permanent, not only in cell culture systems but also in mouse models. For whole-organism studies, the RNA needs to be continuously transcribed from DNA that has been stably integrated into the genome. To do this, researchers have made constructs, which, when transcribed, form a short hairpin RNA (shRNA). This shRNA is processed by Dicer in the cytoplasm to make an siRNA, and the RNAi pathway is triggered. The shRNA constructs lend themselves to large-scale, high-throughput approaches, and several hairpin libraries have been constructed. One such library has been used in a genetic screen to find new members of the p53 pathway, proving that loss-of-function screens utilizing RNAi are not only feasible but also capable of yielding interesting and relevant biological results. shRNA constructs have also been successfully introduced into mouse ES cells and are used to make an RNAi-based knockout mouse.

5.2 RNAi as a Potential Therapeutic

The ability to knockdown a specific gene in somatic cells makes RNAi an attractive approach for therapeutics. Previous nucleic acid–based therapies, such as ribozymes and antisense technology, have largely failed, but RNAi appears to surmount obstacles that have hindered previous methods. Because RNAi is an endogenous process, an entire pathway already dedicated to utilizing siRNAs allows exogenously introduced siRNAs to work at very low concentrations. Especially since drug delivery is a common problem for all molecular therapies, the nanomolar concentrations needed for siRNAs to work (as compared to micromolar concentrations

required for antisense to work) make siRNAs an attractive option. Furthermore, as siRNAs are natural molecules, they greatly reduce toxic side effects, such as is common with chemotherapeutics.

Early work in various model systems showed that RNAi holds the potential for therapeutic use. For example, CCR5 is a coreceptor for HIV, and there is a population of humans who carry a CCR5 allele with a truncation in the protein that confers protection from HIV infection. In cell culture systems, RNAi-mediated knockdown of CCR5 is also able to confer resistance to HIV, thus serving as a proof of principle that RNAi can be used as a successful therapeutic. This idea can also be reversed in the sense of using RNAi not to knockdown a human gene but instead use it to target viral genes that are important for its life cycle, and indeed, experimentation has shown this to be the case for several infectious pathogens, including HIV and influenza. Of course, the theoretical usefulness of RNAi is not limited to viral infections, as any human disease that involves an aberrant or overexpressed gene would be amenable to an RNAi-based treatment.

RNAi is not yet ready to make the leap from bench to bedside, but progress is ongoing in this arena. Several companies are pursuing RNAi-based therapeutics, and mouse models have shown preliminary but intriguing results suggesting that, with time, RNAi will be a powerful means of treating human disease. One recently published example shows that an siRNA chemically modified with a cholesterol moiety can be injected intravenously into mice to silence apoliprotein B. This exciting result illustrates that problems relating to stability, bioavailability, and cellular transport are beginning to be addressed.

Keywords

Chaotropic
Biologically disruptive. Chaotropic lysis buffers disrupt cell and organelle membranes and destroy enzymatic activity on contact.

Complementary DNA (cDNA)
DNA synthesized *in vitro* from an RNA template by an enzyme known as a *reverse transcriptase*. cDNA can be either single- or double-stranded, and is used for RT-PCR, nucleic acid probe synthesis, or library construction. Because cDNA can only be made from transcripts present at the moment of cellular disruption, it is a permanent biochemical record of the cell.

Diethyl Pyrocarbonate (DEPC)
A chemical used to purge reagents of nuclease activity. DEPC is carcinogenic and should be handled with extreme care. See text for details.

Dot Blot (also Slot Blot)
A membrane-based technique for the quantification of specific RNA or DNA sequences in a sample. The sample is usually ''dot'' configured onto a filter by vacuum filtration through a manifold. Dot blots lack the qualitative component associated with electrophoretic assays.

Heterogeneous nuclear RNA (hnRNA)
The primary product of RNA polymerase II transcription in eukaryotic cells. hnRNA alone can be processed and mature into mRNA, which, in turn, is able to support the synthesis of proteins.

Hybridization
The formation of hydrogen bonds between two nucleic acid molecules, which are complementary to some degree. The specificity of hybridization is a direct function of the stringency of the system in which the hybridization is being conducted.

Messenger RNA (mRNA)
The mature product of RNA polymerase II transcription. mRNA is derived from heterogeneous nuclear RNA (hnRNA) and, in conjunction with the protein translation apparatus, is capable of directing the translation of the encoded polypeptide.

Northern Blot Analysis
A technique for transferring electrophoretically chromatographed RNA from a gel matrix, usually agarose, onto a filter paper for subsequent immobilization and hybridization. The information gained from Northern blot analysis is used to qualitatively and quantitatively assess the expression of specific genes.

Nuclear Runoff Assay
A method for labeling nascent RNA molecules in isolated nuclei. The rate at which specific RNAs are being transcribed can then be assayed based upon the degree of label incorporation. See entry for steady-state RNA for comparison.

Nuclease Protection Assay
A method for mapping and/or quantifying RNA transcripts. In general, hybridization between probe and target RNA takes place in solution, followed by nuclease digestion (with S1 nuclease or RNase) of all molecules or parts thereof, which do not actually participate in duplex formation. Nucleic acid molecules, which are locked up in a double-stranded configuration, are relatively safe or protected from nuclease degradation. The undigested RNA:RNA or RNA:DNA hybrids are then precipitated and/or electrophoresed for quantification.

Poly(A)$^+$Tail
A tract of adenosine residues enzymatically added to the 3′ terminus of mRNA by the nuclear enzyme poly(A) polymerase. The addition of a poly(A) tail involves cleavage at the 3′ terminus of the primary transcript followed by polyadenylation.

Polymerase Chain Reaction (PCR)
Primer-mediated enzymatic amplification of cDNA or genomic DNA sequences. This technology revolutionized molecular biology in the early and mid-1990s.

Primer
A short single-stranded nucleic acid molecule, or portion thereof, which can base pair with a complementary sequence and which provides a free 3′-OH for any of a variety of primer extension-related reactions.

Probe
Usually labeled nucleic acid molecules, either DNA or RNA, which is used to hybridize to complementary sequences present among the complexity of different target sequences in a nucleic acid sample, as in the Northern analysis, Southern analysis, or nuclease protection analyses and DNA library screening.

Proteome
The full complement of proteins produced by a cell at a particular time. Proteome maps are typically generated and assessed by 2-D electrophoresis and other techniques designed to identify, quantify, and characterize the products of translation.

Real-Time PCR
A state-of-the-art method for measuring PCR product accumulation as it is produced in each cycle, rather than measuring final product mass at the end of the reaction. Real-time PCR is widely regarded as the premier quantitative PCR-based assay.

Relative Abundance
The quantity of a particular RNA transcript relative to some other transcript in the same sample **or** relative to the amount of the same transcript in other experimentally related samples. This determination is made by hybridization with a complementary nucleic acid (see above).

Ribonuclease
A family of resilient enzymes, which rapidly degrade RNA molecules. Control of ribonuclease activity is a key consideration in all manipulations involving RNA.

RNA (Ribonucleic acid)
A polymer of ribonucleoside monophosphates, synthesized by an RNA polymerase. RNA is the product of transcription.

RNA Interference (RNAi)
RNAi is also known as *posttranscriptional gene silencing*.

RT-PCR
The technology by which RNA molecules are converted into their complementary DNA (cDNA) sequences by any one of several reverse transcriptases, followed by the amplification of the newly synthesized cDNA by standard PCR amplification.

Steady State RNA
The final accumulation of RNA in the cell/cytoplasm. For example, measurement of the cytoplasmic prevalence of a particular species of mRNA in no way relates to the **rate** of transcription or RNA degradation in the cell (see nuclear runoff assay).

Transcription
The process by which complementary RNA molecules are synthesized from a DNA template.

Transcriptome
The complete set of mRNA molecules produced by a particular cell under a particular set of circumstances.

Xenobiotic
A chemical foreign to a biological system.

The cellular biochemistry is reflected in the overall abundance of nuclear and cytoplasmic RNA species, which, inevitably, drive the phenotype of the cell. In order to more readily understand the cellular response to experimental or environmental challenges, various subpopulations of RNA are harvested and characterized to gain insight into the differential expression of genes and possibly the cellular level at which these genes are modulated. The expedient isolation of high quality RNA is essential to support all downstream applications, and the method by which this end is accomplished is dictated by the nature of the biological source material. The goal in a study such as this is to quantify gene expression by measuring the prevalence of one or more RNA species, which are of immediate interest to the investigator, and how these data relate to a control population of RNAs. Methods for RNA analysis are rather diverse and each of these provides a glimpse of some aspect of gene regulation with a characteristic level of sensitivity. Often several RNA methodologies are utilized to provide a more complete picture of the up- and downregulation of specific genes and gene families.

1 Introduction

The isolation and characterization of ribonucleic acid (RNA) from cells and tissue samples is a central and recurrent theme in molecular biology. In particular, the purification of chemically stable and biologically functional RNA is the starting point for the systematic evaluation of the cellular biochemistry by standard molecular techniques such as Northern analysis, nuclease protection (S1 and ribonuclease protection assays), dot blot analysis, nuclear runoff assay, the synthesis of representative cDNA libraries, and all forms of RT-PCR (The polymerase chain reaction (PCR) process is covered by patents currently owned by Roche Molecular Systems, Inc. and F. Hoffmann-LaRoche Ltd. Use of PCR requires a limited license under their patents. PCR must also be performed in an authorized thermal cycler. For specific details contact the Director of Licensing, Applied Biosystems, 850 Lincoln Centre Drive, Foster City, CA 94404.). Because messenger RNA (mRNA) abundance is a useful parameter of gene expression, the expedient recovery of RNA from a biological source is a critical first step for the derivation of meaningful data. Difficulties in the purification, handling, and storage of RNA are intrinsic to the labile chemical nature of these molecules. These difficulties are further compounded by the aggressive character of resilient ribonucleases (RNase), the apparent ubiquity of which is undisputed. Indeed, the novice quickly learns of the absolute requirement for management of RNase activity at each level of RNA isolation and characterization. Failure to do so will almost certainly compromise the integrity of the resulting RNA and its probable utility.

2 Subpopulations of RNA

Prior to the onset of cellular disruption, the investigator must determine which RNA subpopulation is of experimental interest.

For example, the precise questions being asked of a particular set of experiments may require characterization of total cellular RNA, cytoplasmic RNA alone, nuclear RNA alone, poly(A)$^+$ RNA, or poly(A)$^-$ RNA. Transcriptional activity is generally assayed using one of the methods described below, for example, Northern analysis, and the data is then validated using another method, such as nuclease protection or RT-PCR.

2.1 Total Cellular RNA

Total cellular RNA is generally isolated when it is necessary to assess the transcriptional activity of a gene (is the gene transcribed and to what extent?) by any of the methods delineated below. The isolation of total cellular RNA is usually easier and more rapid compared to other isolation strategies. Because purified total cellular RNA consists of both nuclear RNA and cytoplasmic RNA, it is impossible to determine the relative contribution of each. Most of the kits and reagents, which favor rapid isolation in less than 30 min, yield either total cellular RNA or total poly(A)$^+$ RNA (both mRNA and hnRNA). The disadvantage of working with populations of total cellular RNA is that the investigator is generally unable to determine the relative contribution of RNA from the nucleus and the cytoplasm. This distinction may or may not be important in the context of a particular investigation.

2.2 Total Cytoplasmic RNA

Total cytoplasmic RNA (predominantly rRNA, tRNA, mRNA) is generally isolated when assessment of posttranscriptional regulation of genes is being investigated. Purification of cytoplasmic RNA can also be a method of enrichment, that is, by noninclusion of the nuclear RNA, the percentage of the total mass of RNA in a sample that mRNA represents is increased. Further enrichment can be accomplished via the selection of poly(A)$^+$ mRNA, as described below.

2.3 Nuclear RNA

Nuclear RNA is often studied in conjunction with the independent characterization of cytoplasmic RNA as a means of assessing the level (transcriptional vs posttranscriptional) and degree of regulation of various genes. It is well documented that a large mass of transcribed RNA is degraded in the nucleus; this precursor RNA never matures into mRNA capable of supporting translation in the eukaryotic cytoplasm. By comparing the nuclear abundance and cytoplasmic abundance of a particular RNA, a cause–effect relationship may be discerned between an experimental manipulation and the regulation of gene expression in that system with respect to RNA biogenesis because hnRNA, produced by RNA polymerase II, matures into mRNA. The analysis of nuclear RNA may also be performed in order to study the rate at which genes are transcribed (nuclear runoff assay, below), as opposed to the assay of steady-state RNA levels, data that can be used to clarify the assessment of the level of regulation of gene expression.

2.4 Poly(A)$^+$ RNA

Poly(A)$^+$ RNA can be purified from previously isolated cellular RNA, cytoplasmic RNA, or directly from whole cell lysates.

This approach is generally taken for one of two fundamental reasons. First, a sample of poly(A)$^+$ mRNA is often assumed to reflect the biochemical and physiological status of the cell. By eliminating rRNA, tRNA, and large, unspliced nuclear RNA species, improved sensitivity and resolution in the assay of specific mRNAs is greatly favored. Secondly, purified poly(A)$^+$ mRNA is the template material for *in vitro* synthesis of complementary DNA (cDNA). While cDNA can be synthesized from total RNA, exclusion of the highly abundant rRNA and tRNA species from the synthesis reactions generates cDNA which is far more representative of the cellular biochemistry at the moment of cellular disruption. Poly(A)$^+$ mRNA may be purified by affinity chromatography using oligo(dT)$_{12-18}$ linked to one of several popular matrices, including paramagnetic beads, biotin, cellulose beads, or microcrystalline cellulose. It is important to note, however, that transcript enrichment performed to increase sensitivity may actually be counterproductive in some cases because the loss of some mRNA during the enrichment procedure may serve only to further underrepresent very low-abundance mRNA. Due in no small measure to the power of PCR and the clever design of the required primers, poly(A)$^+$ selection is viewed by many investigators as unnecessary for most contemporary applications.

2.5 Poly(A)$^-$ RNA

Poly(A)$^-$ RNA is that subpopulation of RNA lacking the tract of adenosine residues, which characterizes the 3′ terminus of a majority of eukaryotic mRNAs. The predominant members of this class include rRNA, tRNA, as well as a small family of naturally nonpolyadenylated mRNAs, of which, the histone mRNAs are a noteworthy example. In instances where poly(A)$^-$ mRNA might not be detected due to exclusion from a sample, either the poly(A)$^-$ fraction or a sample of total RNA from the same biological source will contain these naturally nonadenylated transcripts for assay, assuming their respective genes are transcriptionally active. Moreover, depletion of poly(A)$^+$ mRNA from a sample renders the resulting poly(A)$^-$ fraction an excellent negative control in the assay of poly(A)$^+$ mRNA species.

3 Goals in the Purification of RNA (adapted, in part, from Farrell, 1993; 1998; 2005)

Proper and thoughtful planning prior to the onset of lab work is an absolute requirement for the recovery of high quality RNA capable of supporting further biochemical analysis. In the preliminary stages, an experimental design for the purification of nucleic acids in general must address five specific goals, the successful achievement of each of these, in order, will influence profoundly the yield, quality, and utility of the sample.

Goal 1: Select an appropriate method for membrane solubilization. The first decision factoring into an RNA isolation strategy is based upon which population of RNA or subcellular compartment the investigator wishes to study. For example, an investigator may wish to determine whether the observed modulation of gene expression in a model system is regulated transcriptionally or by some posttranscriptional event(s). In such an instance, selection of the method of cellular disruption and subsequent RNA isolation must permit

analysis of salient nuclear transcripts independently of those localized in the cytoplasm. The method of cell lysis will determine the extent of subcellular disruption in a sample, and is a direct function of the lysis buffer. For example, a lysis buffer that is used successfully with tissue culture cells may be entirely inappropriate for whole tissue samples. Further, the method by which membrane solubilization is accomplished will dictate which additional steps will be required to remove DNA and protein from the RNA preparation, and whether compartmentalized nuclear RNA and cytoplasmic RNA species can be purified independently of one another. While DNA can be purged from an RNA preparation with minimal fanfare, it is virtually impossible to determine the relative contribution of transcripts from the nucleus and from the cytoplasm once RNA from these two subcellular compartments have mingled and copurified. A particular lysis procedure must likewise demonstrate compatibility with ensuing protocols. The take-home lesson is to always think two steps ahead: the proper method of solubilization is dependent upon the plans for the RNA after purification and the questions being asked of a particular study.

Goal 2: Ensure total inhibition of nuclease activity. The imperative for controlling nuclease activity is nonnegotiable. This includes purging RNase from reagents and equipment (extrinsic sources of nuclease activity) and controlling RNase activity in a cell lysate (intrinsic source of nuclease activity). While some lysis reagents inhibit nuclease activity in their own right (harsh lysis buffers, below), other lysis reagents require additional nuclease inhibitors (gentle lysis buffers, below) to safeguard the RNA during the isolation procedure. With respect to long-term storage of purified RNA, it is incumbent upon the investigator to ensure that added ribonuclease inhibitors will not interfere with any subsequent manipulations and/or reactions involving the RNA.

Goal 3: Remove contaminating proteins from the sample. The complete removal of protein from a cellular lysate is of paramount importance in the isolation of both RNA and DNA. Meticulous attention to this detail is required both for accurate quantification and precision in hybridization. The removal of proteins from nucleic acid samples may be accomplished by

1. protein hydrolysis with proteinase K;
2. salting-out of proteins;
3. solubilizing proteins in guanidinium-based buffers;
4. repeated extraction with mixtures of phenol and chloroform;
5. any combination of the above.

RNA molecules are not as fragile as high molecular weight DNA; thus, more aggressive methods can be employed for removal of proteins, including the use of phenol:chloroform. While deproteinization is itself a means of controlling ribonuclease activity, purified RNA samples will be once again susceptible to nuclease degradation following removal of the protein denaturant.

Goal 4: Concentrate the sample. This is the final step in nearly all RNA purification schemes. The most versatile method for concentrating nucleic acids is precipitation using various combinations of salt and alcohol, such as the very common method of adding sodium acetate and ethanol. Nucleic acids and the salt that drives their precipitation form complexes that have greatly reduced solubility in high concentrations of alcohol. Further, the rate of precipitation appears to be temperature dependent. Unlike the precipitation

of genomic DNA, the precipitation of RNA often requires longer incubation periods at −20°, a phenomenon that is a direct function of the complexity of cellular RNA. In general, greater g-forces must be applied in order to completely recover an RNA precipitate for subsequent analysis. Other concentration procedures include the use of commercially available concentrating devices, dialysis, centrifugation under vacuum, and binding to silica matrices in high salt. These methods are less frequently employed for RNA work because the degree of success is much more dependent upon the skill of the investigator and equipment availability than is the case with simple salt and alcohol concentration.

Goal 5: Select the proper storage conditions for the purified RNA. Because of the naturally labile character of RNA, improper storage of excellent RNA samples will often result in degradation in a relatively short time. There are many opinions as to the proper temperature, buffer, and storage form for RNA. As a general rule, RNA is most stable as an ethanol precipitate at −80°. Large samples or RNA stocks should be stored in convenient aliquots in order to avoid repeated freeze–thaw cycles.

4
Methods of Cellular Disruption

As suggested above, in order to select a suitable method for cellular disruption or ''solubilization,'' consideration must be given as to which subpopulation of RNA is desired for study as well as the nature of the biological material (i.e. cells grown in tissue culture vs whole tissues). Lysis buffers are generally categorized as either ''gentle'' or ''harsh.''

4.1
Gentle Lysis Buffers

Gentle lysis buffers are used when a specific subpopulation of RNA is desired (e.g. cytoplasmic RNA alone) and nuclear integrity must be maintained. Gentle lysis buffers, often slightly hypotonic, frequently contain the nonionic detergent NP-40 (Nonidet™ P-40 (Nonidet P-40 is a registered trademark of the Shell Company.); now known as *Igepal CA-630*). Because osmotic lysis is the gentlest form of cellular disruption, NP-40 lysis buffers are ideal for the solubilization of the plasma membrane alone, and the inclusion of low concentrations of magnesium helps maintain nuclear integrity. Thus, the nucleus and its contents (DNA and nuclear RNA) can be separated from the cytosol by differential centrifugation. The resulting supernatant is rich in cytoplasmic RNA and proteins, the latter of which are easily removed by repeated extraction with phenol: chloroform. If desired, the nuclear pellet may be processed separately for the recovery of nuclear transcripts. This method of cellular disruption is ideally suited for cells harvested from tissue culture. However, owing to the complex geometry and formidable nature of whole tissue samples, NP-40-containing lysis buffers do not work well with tissue samples unless coupled with limited, non-shearing homogenization.

The obvious advantage of this isolation strategy is that the material precipitated at the end of the procedure is cytoplasmic RNA. A disadvantage to using this approach is that the lysis buffer alone is not sufficiently inhibitory toward RNase. Upon cellular lysis, normally sequestered ribonucleases are liberated, the activity of which will greatly compromise the integrity of the RNA even as the investigator

is working diligently to purify the same. It is very helpful to keep the sample on ice at all times, unless the protocol specifically dictates otherwise; it is likewise helpful to use ice-cold reagents and tubes, which have been prechilled on ice prior to use. If desired, an exogenous RNase inhibitor (below) can be added to the lysis buffer.

4.2 Harsh Lysis Buffers

There is probably no better way to deal with seemingly recalcitrant ribonucleases than to disrupt cells in guanidinium lysis buffer. Upon contact, guanidinium-containing buffers distort the tertiary folding of ribonucleases, resulting in the inactivation of these enzymes (other chaotropic lysis buffers, which contain high concentrations of SDS have also been described). The inclusion of additional ribonuclease inhibitors to such lysis buffers is not necessary, and these procedures for RNA isolation are usually performed at room temperature.

In the presence of chaotropic agents, organelle lysis accompanies disruption of the plasma membrane. Thus, nuclear RNA, genomic DNA, and mitochondrial DNA all copurify with the cytoplasmic RNA, requiring additional steps to remove DNA from the sample. In the past, the most prevalent of these methods was isopycnic centrifugation, involving centrifugation through a cesium chloride (CsCl) gradient or cesium trifluoroacetate (CsTFA) gradient. Isopycnic separation is possible because of the differing buoyant densities of DNA (1.5–1.7 g/mL) versus RNA (1.7–2.0 g/mL).

The differential partitioning of DNA, RNA, and protein by acid-phenol extraction was first described by Chomczynski and Sacchi (1987), changing the way the RNA and DNA are separated from each other in a whole-cell lysate or tissue homogenate. The investigator can fully exploit the salient chemical differences between RNA and DNA in an acidic environment and by the judicious blending of organic solvents. Organic extraction of nucleic acids at acidic pH causes DNA partitioning to the interphase and organic phase while RNA remains in the aqueous phase. This approach precludes the requirement for ultracentrifugation and greatly reduces the required amount of hands-on time, to the obvious benefit of the investigator. The popularity of this general approach has resulted in the development of a number of nucleic acid isolation reagents, which support the unceremonious purification of RNA from both tissue and tissue culture cells alike.

In order to take full advantage of the disruptive nature of the guanidinium isolation procedures and still maintain the subcellular compartmentalization of RNA, one worthwhile strategy is to begin the isolation procedure with gentle NP-40 lysis, followed by recovery of intact nuclei, which are then lysed with guanidinium buffer. The purification of nuclear (or cytoplasmic) RNA then proceeds as if working with intact cells. This approach is particularly suited for the isolation of nuclear RNA for Northern analysis.

The principal drawback to these chaotropic methods is that the investigator is not able to discriminate between cytoplasmic and nuclear RNA, as there is no method by which to separate nuclear RNA from mRNA, once mixing has occurred (size fractionation may result in a partial separation). Moreover, it is unfortunate that many seasoned investigators begin to show signs of sloppiness with respect to the control of RNase activity when routinely working with guanidinium buffers. While

it is true that RNA is safe from nuclease degradation in the presence of these agents, purified RNA is once again susceptible to nuclease degradation.

5 Inhibition of Ribonuclease Activity

The difficulties associated with the isolation of full-length, intrinsically labile RNA are further compounded by the ubiquitous RNase activity. RNases are a family of enzymes, which degrade RNA molecules through both endonucleolytic and exonucleolytic activity. Particularly resilient are ribonucleases of the pancreatic variety. These small, remarkably stable enzymes resist denaturation under conditions that would easily purge other enzyme activities, including pH extremes and autoclaving. It is clearly incumbent upon the investigator to ensure that both equipment and reagents are purged of nucleases from the onset of an experiment. For most RNA-minded molecular biologists, saying that a reagent or apparatus is sterile is more than likely a statement that it is ribonuclease free.

The method selected for controlling ribonuclease activity must, first and foremost, demonstrate compatibility with the cell lysis procedure. Nuclease inhibitors are most often added to gentle lysis buffers when subcellular organelles (nuclei especially) must be purified intact, as in the independent examination of nuclear RNA and cytoplasmic RNA. Secondly, the method of nuclease inhibition must support the integrity of the RNA throughout the subsequent fractionation or purification steps, some of which may require several hours. Thirdly, the reagents used to inhibit ribonuclease activity must be easily removed from purified RNA so as not to interfere with subsequent manipulations. In all cases, and especially when characterizing a new cell type or model system for the first time, actions taken to control nuclease activity should be aggressive if not compulsive. Failure to do so is likely to yield a useless sample of degraded RNA.

5.1 Preparation of Equipment and Reagents

Rule number one when working with RNA is to wear gloves during the preparation of reagents and equipment and especially during the actual RNA extraction procedure. Finger greases are notoriously rich in ribonuclease and are generally accepted as the single greatest source of ribonuclease contamination. Further, one should not hesitate to change gloves several times during the course of an RNA-related experiment; door knobs, micropipettes and refrigerator door handles, containers in which chemicals are packaged, nonsterile deionized H_2O, gel electrophoresis boxes and combs, and microbial/fungal growth are also potential sources of nuclease contamination.

With respect to laboratory consumables, any plasticware that is certified as being tissue-culture sterile is always preferred for RNA work. This includes individually wrapped serological pipettes and conical 15 mL and 50 mL tubes. In any event, these items should be handled only with gloves. Bulk packed polypropylene products (microcentrifuge tubes and micropipette tips) are potential sources of nuclease contamination, mainly due to handling and distribution with ungloved hands from a single bag. It is best to purchase these consumables certified as being both DNase- and RNase-free. Any plastic product or other implement that will come into contact with an RNA sample at any time, either

directly or indirectly, and which can withstand autoclaving should be so treated and set aside exclusively for RNA work.

When plasticware is avoided and glassware must be used, as with organic reagents such as phenol and chloroform, individually wrapped borosilicate glass pipettes are strongly preferred. Glassware, which must be reused, should be set aside for RNA work and not be in general circulation in the laboratory. Contrary to popular belief, the temperature and pressure generated during the autoclaving cycle are usually not sufficient to eliminate all ribonuclease activity. Fortunately, ribonucleases can be destroyed quite effectively by baking in a dry heat oven: rinse glassware with ribonuclease-free water (see below) and then bake for 3 to 4 h at 200°. Baking pertains to glassware alone; questions regarding the heating of plastics or other materials can usually be answered by the manufacturers' technical assistance department.

5.2 Inhibitors of RNase

Endogenous ribonuclease activity varies tremendously from one biological source to the next, and the degree to which action must be taken to inhibit nuclease activity is a direct function of cell type. Knowledge of the extent of intrinsic nuclease activity is derived from two principal sources, namely, the salient literature and personal experience.

The method of ribonuclease inhibition is to a great extent a function of the type of lysis buffer. Whereas nondenaturing, osmotic lysis buffers require the inclusion of a nuclease inhibitor, strongly denaturing (chaotropic) lysis buffers generally do not. Such chaotropic compounds include guanidinium thiocyanate, guanidinium HCl, sarcosyl, SDS, 8-hydroxyquinoline, CsCl, CsTFA, and/or various formulations of organic solvents.

Vanadyl ribonucleoside complexes (*VDR; VRC*) were at one time a popular addition to lysis buffers, which alone are ineffective in the control of ribonuclease, as in the popular nonionic NP-40 method. These complexes function as transition state analogs. In the absence of VDR, RNase-mediated cleavage of the phosphodiester backbone of RNA results in the transient formation of a dicyclic transition state intermediate that is subsequently opened by reaction with a water molecule. In its capacity as an RNA analogue, the vanadium complex forms a highly stable dicyclic species to which the enzyme remains irreversibly bound. Thus, nuclease activity is eliminated by locking ribonuclease and "pseudosubstrate" in the transition state. VDR binds tightly to a broad spectrum of cellular ribonucleases including RNase A and RNase T1, but not RNase H, and is compatible with a variety of cell fractionation methods. VDR should be used selectively, however, as even trace carryover quantities are sufficient to inhibit *in vitro* translation of purified mRNA and can also interfere with reverse transcriptase activity, thereby excluding its use with any RT-PCR applications. For this reason, the use of VDR as an RNase inhibitor has fallen out of favor with most molecular biologists.

RNasin® (Promega) may be used to inhibit nuclease activity and circumvent some of the problems commonly associated with the use of VDR. RNasin® inactivates RNase A, RNase B, and RNase C, but not RNase T1, S1 nuclease, nor RNase from *Aspergillus*, and is compatible with a variety of *in vitro* reactions. Care must be taken to avoid strongly denaturing

conditions, which can cause the uncoupling of RNase-RNasin® complexes and restoration of RNase degradative activity.

Diethyl Pyrocarbonate (*DEPC*) is an efficient, nonspecific inhibitor of ribonuclease. It is used to purge reagents of nuclease activity because of the unreliability of autoclaving alone. DEPC is typically added to stock solutions and buffers to a final concentration of 0.05 to 0.1% (v/v); buffers are then shaken or stirred for at least 2 h. Finally, DEPC must be completely destroyed by autoclaving or by maintaining the solutions at 60° overnight. The complete removal of DEPC from buffers and reagents is important because trace amounts of DEPC will result in chemical modification of adenine residues, thereby changing many of its physical properties, including strong inhibition of the polymerase chain reaction. Precautions indicated by the manufacturer must be observed when handling this material, as it is carcinogenic and potentially explosive.

DEPC should *never* be added to any buffer containing tris or mercaptans, with which DEPC is reactive. Instead use DEPC-treated water (add DEPC to water; autoclave to remove DEPC) to make up the tris-containing solution and then autoclave again. Alternatively, buffers consisting of chemicals, which demonstrate DEPC incompatibility, can be twice filtered through a nitrocellulose membrane to remove RNase activity and other trace proteins. Moreover, an electrophoresis apparatus (gel comb, casting tray, or gel box) should never be exposed to DEPC, as acrylic is not DEPC-resistant. Alternatively, various types of laboratory plastics can be rinsed briefly in a 3% solution of H_2O_2, and then rinsed with copious volumes of sterile H_2O. As a powerful oxidizing agent, hydrogen peroxide very effectively destroys RNase activity on many common laboratory surfaces. The use of DEPC has fallen out of favor due to the widespread availability of nuclease-free reagents and stock solutions from most vendors.

Many ribonucleases manage to renature following removal of many denaturing reagents; therefore it is prudent to maintain separate containers of chemicals and stock solutions for exclusive use as RNA reagents. Chemical solids should be weighed out with a ribonuclease-free spatula and stock solutions should be aliquoted into suitable volumes. Aliquots used once should be discarded. While such actions may at first seem to be excessive, they may well preclude the accidental introduction of ribonucleases and facilitate recovery of the highest possible quality RNA.

6 Methods for the Analysis of RNA

Evaluation of the cellular biochemistry by hybridization of RNA is possible in conformity with many of the parameters associated with the analysis of DNA. Methods range from the traditional to the contemporary and each of these has applicability under a defined set of experimental conditions. For the convenience of the reader, the relative merits of three of the standard methods are presented in Table 1.

6.1 Northern Analysis

The quintessential method for the assay of gene expression is a method properly known as *Northern analysis* (also known colloquially as *Northern blotting*, the Northern blot analysis and/or RNA blot analysis). In this technique, purified RNA is resolved

Tab. 1 Comparison of the traditional Northern analysis, nuclease protection assay, nuclear runoff assay, and RT-PCR.

	Northern analysis	***Nuclease protection assay***	***Nuclear runoff assay***	***RT-PCR***
Advantages	Provides a qualitative component to RNA analysis. Supports several rounds of hybridization with different probes. Is compatible with total, cytoplasmic, or poly(A)$^+$ RNA. RNA is relatively stable on filter. Is able to assess integrity of the sample.	Much higher sensitivity than Northern analysis. Requires less handling of RNA than other types of analysis. Is tolerant of partially degraded RNA. Solution hybridization is more quantitative than filter hybridization. Can be used for steady-state or transcription rate assays.	Characterizes relative rate of transcription. Natural geometry of the chromatin is maintained. Permits simultaneous study of several genes. Can be used to discern transcriptional vs posttranscriptional gene regulation when used in conjunction with data from Northern analysis.	Provides unparalleled sensitivity when properly designed. Provides unparalleled resolution. Supersedes many of the classical techniques. Minimizes the amount of handling of the RNA. Very rapid technique. Favors research productivity.
Disadvantages	Is the least sensitive assay. Denaturants can be toxic. Requires extensive handling of RNA. Is a time-consuming process. Provides ample opportunity for RNase degradation. Characterizes only steady-state RNA.	Protected fragment is smaller than native RNA. Nucleases, especially S1, can be difficult to control. Assay is more sensitive to exact hybridization parameters than other assays. Double-stranded probes can compromise quantitativeness of the assay if reannealing occurs.	Nuclear isolation requires a fair amount of skill. Probe complexity is very large. Unlabeled endogenous RNA can compete with labeled RNA during hybridization. Mechanics of the assay support transcript elongation, and not initiation, during labeling.	Much more sensitive to the precise reaction components and conditions than the other assays. Exquisitely sensitive to contaminants, especially genomic DNA. Carryover contamination must be addressed. Optimization can be time-consuming and costly.

From Farrell Jr., R.E. (2005) *RNA Methodologies: A Laboratory Guide for Isolation and Characterization*, 3rd edition, page 389. With permission from Elsevier.

electrophoretically under denaturing conditions and subsequently transferred or "blotted" onto a solid filter support (the so-called "filter membrane"). The RNA on the blot is then hybridized to an appropriately labeled nucleic acid probe, which will support subsequent detection by autoradiography or by chemiluminescence. Because samples of RNA are electrophoresed prior to hybridization, the Northern analysis provides both a quantitative and qualitative biochemical profile of the sample; denaturation of the RNA prior to electrophoresis is necessary to ensure that migration of the sample through the gel occurs only with respect to molecular weight and is not distorted by the formation of the secondary structure commonly associated with single-stranded molecules so that the overall length of the transcript(s) can be determined, a datum, which cannot be discerned using other methods.

The objective of Northern analysis is to quantify gene expression by detecting the relative abundance of those mRNAs in the sample, which are of immediate interest to the investigator. Whereas in the Southern analysis, the resulting data pertains to the structure and organization of genes, data derived by Northern analysis reflects the transcriptional activity of genes.

The principal concern of many in the assessment of Northern blot data is the limited sensitivity of the assay. Few would argue against the notion that the physical application and immobilization of an RNA sample onto a filter membrane renders some of those molecules incapable of/unavailable for base pairing to a complementary nucleic acid probe. Moreover, the Northern analysis is by no means intended to discern the absolute mass of RNA in the cell. Such data may be measured far more accurately by solution hybridization-based methods, especially real-time PCR. Hence, data derived from the Northern analysis must be interpreted in the context of the relative abundance of a particular RNA amongst all of the samples involved.

The electrophoresis of RNA is itself an important diagnostic tool. A great deal can be learned about the integrity and probable utility of an RNA sample upon examination of a representative aliquot. RNA has a very characteristic profile on a denaturing gel (Fig. 1). The appearance of the predominant species, the 28S and 18S ribosomal RNAs (rRNA) is an indicator of the integrity of the sample. Ideally, a very light smearing above, between, and just barely below the rRNAs indicates that the sample is enriched in undergraded RNA and is probably capable of supporting nucleic acid hybridization. Heavier smearing, especially below the level of the 18S rRNA, is quite ominous, being indicative of partially degraded RNA. The complete absence of the ribosomal RNAs indicates a completely degraded sample. As it is obviously desirable to ascertain the integrity of a sample before moving on to sophisticated and often time-consuming techniques, a brief period of electrophoresis to assess the quality of the sample should be the standard operating procedure in any molecular biology setting.

6.2 Nuclease Protection Assay

The intrinsic shortcomings of the Northern analysis mandate a different format for the assay of gene expression when very exacting quantitative data is required. In contrast to the assay method of the Northern analysis, at the heart of assay by nuclease protection is high stringency hybridization of target and probe

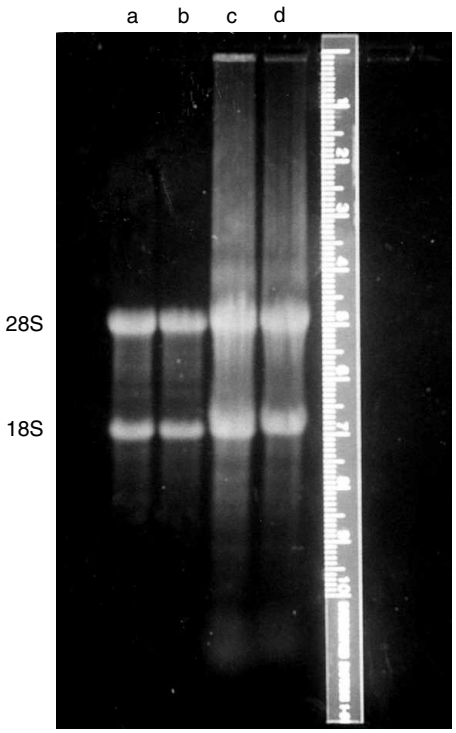

Fig. 1 Assessment of the integrity of RNA samples. The sharp definition of the 28S and 18S rRNA species in lanes a and b demonstrates the integrity of the sample. RNA in lanes c and d is also high quality, although an excessive amount of RNA was applied to these lanes. Lanes a and b: 20 µg of total cytoplasmic RNA prepared by NP-40 lysis. Lanes c and d: 25 µg of total cellular RNA (nuclear and cytoplasmic), prepared by guanidinium-acid-phenol extraction. Note the higher molecular weight nuclear RNA species in the sample. (From Farrell Jr., R.E. (1993) *RNA Methodologies: A Laboratory Guide for Isolation and Characterization*, Academic Press, San Diego, CA), p. 60. Reproduced with permission.

molecules, which are both free-floating in solution (solution hybridization) as opposed to having the target mRNA fixed on the filter paper (mixed phase hybridization). Driving solution hybridization are random molecular collisions, the kinetics of which are related directly to the total mass of nucleic acid in the reaction tube (probe + target + carrier = total mass). Presumably, all complementary nucleic acid molecules are capable of hybridization. The S1 nuclease protection assay and the ribonuclease (RNase) protection assay are methods of greatly enhanced sensitivity and resolution, and are universally considered to be more quantitative than Northern analysis.

The best nucleic acid probes for these assays are substantially shorter than the target mRNA. Upon molecular hybridization, a short double-stranded region is generated; the 5′ and 3′ regions of the target molecule flanking the double-stranded area remain single stranded. The enzyme S1 nuclease or a combination of RNases is then used to digest all nucleic acid molecules, which did not participate in nucleic acid hybridization. Only double-stranded nucleic acid molecules are resistant to nuclease attack and remain intact during incubation with these enzymes (Fig. 2). The resulting product of this assay, the so-called protected fragment, is then resolved by electrophoresis. By virtue of the mechanics of this assay, the size of the protected fragment is expected to be similar to the size of the probe sequence itself, which is often substantially shorter than the native RNA target. The protected fragment is then visualized

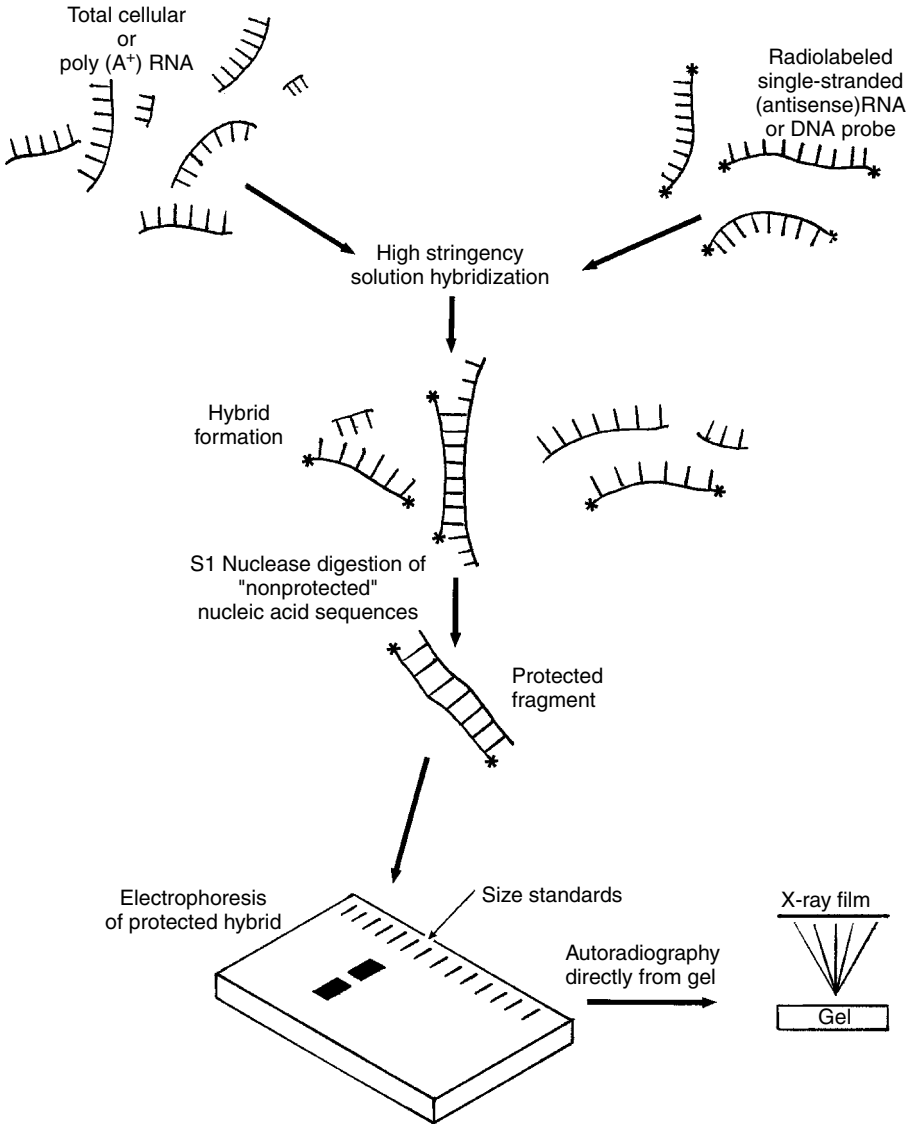

Fig. 2 Schematic of the S1 nuclease assay for the quantitation of specific RNA species. Purified RNA is hybridized in solution with a labeled, complementary sequence to form thermodynamically stable hybrid molecules. Any RNA and probe species that do not participate in the formation of hybrid molecules are digested away by the single-strand-specific nuclease S1, followed by electrophoresis of the intact hybrid molecules. In the case of an antisense RNA probe, an RNase cocktail can be used to produce the protected fragment (RNase protection assay). The size and abundance of protected RNAs are then deduced by autoradiography directly from the gel. (From Farrell Jr., R.E. (1998) *RNA Methodologies: A Laboratory Guide for Isolation and Characterization*, 2nd edition, Academic Press, San Diego, CA, p. 387). Reproduced with permission.

by autoradiography. As a direct result of solution hybridization and digestion of all nonhybridized nucleic acid molecules, the investigator can expect at least a tenfold enhancement in sensitivity compared to Northern analysis, particularly when performed using antisense RNA probes.

6.3 Dot Blot Analysis

The isolation of high quality RNA from tissue culture cells and whole cell samples is merely the first (although the most critical) step in the evaluation of a model system. Northern analysis, nuclease protection analysis, conversion into cDNA, and so forth can be a time-consuming and expensive road to travel and should not immediately be deemed necessary. When evaluating a model system, cell type, or experimental regimen for the first time, it may be worthwhile to quantify mRNAs of interest by dot blot analysis. This simple technique allows the investigator to make definitive statements about the biochemical composition of a sample without investing excessive man-hours and laboratory resources.

In order to dot blot RNA, denatured samples are applied directly onto a membrane under vacuum using a multiwell dot blot (Fig. 3) filtration manifold. Samples are immobilized onto the surface of the membrane, followed by nucleic acid hybridization. Thus, dot blots and a closely related variant known as *slot blots*, permit rapid detection of the relative amount of a particular RNA in a sample. Salient information can be obtained from purified RNA samples or whole cell lysates without electrophoresis, cDNA synthesis, or synthesis mediated by the polymerase chain reaction. These methods are reserved for later, more exacting analysis of a system after preliminary information has been derived.

Dot blotting is an excellent method for the analysis of gene expression when large numbers of samples are to be evaluated simultaneously, such as an experiment requiring numerous time points. If sample dilutions are desired, they may be arranged either vertically or horizontally. The degree of hybridization is then assessed using image analysis software.

Dot blot analysis yields purely quantitative data. The main drawback of this

Fig. 3 Minifold I dot blot apparatus. Sample dilutions are applied under vacuum directly to the surface of the filter membrane resting beneath the faceplate. (Photo courtesy of Schleicher & Schuell, Inc., Keene, NH).

approach is that it lacks the qualitative component, which accompanies electrophoresis. In order to be truly reliable, dot blot analysis must include excellent positive and negative controls in order to demonstrate hybridization specificity and to gauge nonspecific probe binding to the filter membrane. Moreover, good internal controls are always in order: one should observe equally intense signals from wells into which equal amounts of positive control target was applied. When attempting this type of blot analysis for the first time or with a new system, it is strongly suggested that dilutions of the positive control target material be made in order to determine the linear range of the assay. For example, it would be useless, quantitatively speaking, if the hybridization signals were too intense to be accurately measured on X-ray film, which also has a defined linear range.

6.4 Transcription Rate Assays

The modulation of key regulatory molecules is an integral cellular response to both intracellular and extracellular challenge. One fundamental goal in the assessment of any biological model system is the elucidation of the level of gene modulation. While potential levels of regulation are infinite, they are broadly categorized as transcriptional or due to some posttranscriptional event. The initial characterization of these systems commonly involves isolation, hybridization, and subsequent detection of specific RNA species by dot blot, Northern blot, and nuclease protection analysis. While these approaches may furnish excellent qualitative and quantitative data with respect to steady-state levels of message, that is, the final accumulation of RNA in the cell, RNA prepared by total cellular lysis does not provide information about the rate of transcription, the intracellular compartmentalization (nuclear or cytoplasmic) of the RNA under investigation, or the translatability the RNA in the cytoplasm. Knowledge of this aspect of the cellular biochemistry is necessary to elucidate the level of gene regulation because many mRNAs naturally have much longer half-lives than others, and because the half-life of many mRNA species can be modified in response to a particular xenobiotic regimen or environmental stimulus.

In order to address these questions, two basic approaches have been employed to study the mechanism of transcription and the processing of the resulting transcripts in eukaryotic cells. In one approach, the rate of transcription is measured in intact nuclei by the incorporation of labeled precursor nucleotides into RNA transcripts initiated on endogenous chromatin at the time of nuclear isolation. Elongated, labeled nuclear RNA is then purified for hybridization to complementary, membrane-bound DNA sequences. This widely used technique is known as the *nuclear runoff assay* (Fig. 4). It is a superbly sensitive method for measuring transcription rate as a function of cell state. Because the RNA transcripts are radiolabeled, rather than the probes used to quantify their abundance, the basic format of this assay may be likened to a ''reverse dot blot'' since the probe is membrane-bound and nonradiolabeled. Another technique utilizes specific cloned DNA fragments as templates for transcription and is used to dissect the factors (cellular, ionic, etc.) and sequences necessary for faithful transcription *in vitro* using whole cell extracts.

The principal advantage of the nuclear runoff assay is that labeling occurs whilst

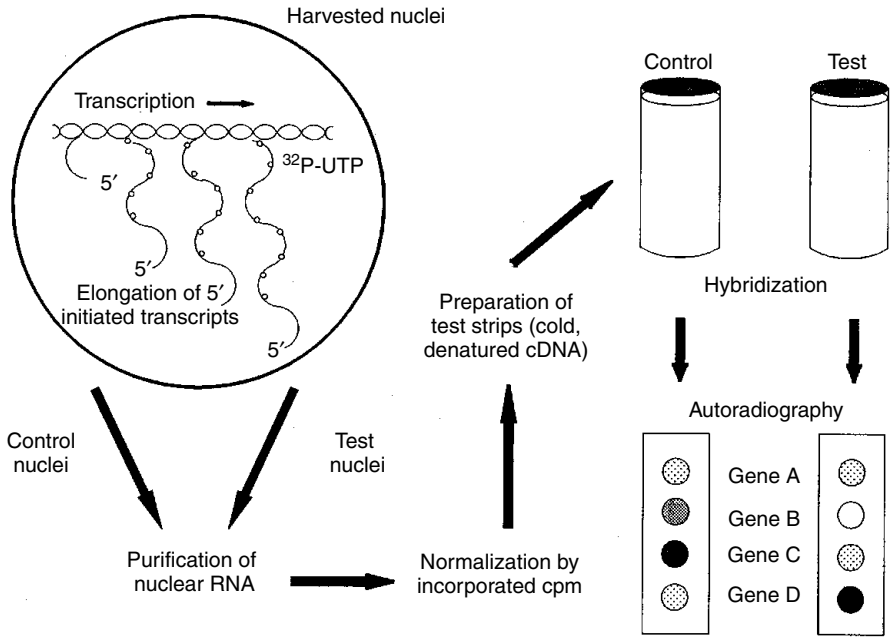

Fig. 4 Nuclear runoff assay. Relative rate of transcription of all genes can be assessed by incubation of intact nuclei with an NTP cocktail containing labeled UTP. Elongated, radiolabeled transcripts are then hybridized to cold cDNA probes immobilized on a nylon filter. Upon autoradiography, the intensity of the signal from each dot is indicative of the degree of label incorporation and thus the relative rate of transcription of specific genes under a define set of experimental conditions. (From Farrell Jr., R.E. (1998) *RNA Methodologies: A Laboratory Guide for Isolation and Characterization*, 2nd edn., p. 411.) With permission from Elsevier.

maintaining the natural geometry of the transcription apparatus. The mechanics and reaction conditions of the nuclear runoff assay promote the elongation of initiated transcripts, but are not believed to support new initiation events. The degree of labeling of any particular RNA species (and hence, the relative transcription rate of specific genomic sequences) may then be assessed by Cerenkov counting (a specific type of radioactive detection) coupled with autoradiography. These data correlate directly with the number of RNA polymerase molecules engaged in transcribing a specific gene and indirectly with the transcriptional efficiency of regulatory sequences associated with the gene under a defined set of experimental conditions. When used in conjunction with the Northern blot analysis of cytoplasmic RNA species (above), data from the nuclear runoff assay may be used to assess whether observed gene modulation is a result of a change in the synthesis (transcriptional control) or a change in splicing/nucleocytoplasmic transport/mRNA stability (posttranscriptional control).

The nuclear runoff assay permits the simultaneous analysis of several genes, all of which are presumably transcribed in the same relative amounts in isolated nuclei as in intact cells. The most critical parameter by far is the preparation of nuclei prior to labeling: success of the nuclear runoff assay is almost entirely

dependent upon the speed with which nuclei are harvested and radiolabeled with precursor UTP. Failure to generate high specific activity RNA probe is usually a direct result of inexperienced handling of the nuclei prior to the labeling step. Nuclei are most often isolated by incubation of cells in NP-40-containing, hypotonic lysis buffer, in iso-osmotic sucrose buffer containing Triton X-100, or by nonaqueous methods. Nuclear purification must also be carried out in such a way as to preserve RNA polymerase activity and nuclear structure during the isolation from cells cultured *in vitro* or, if absolutely necessary, from tissue. Harvested nuclei are then labeled immediately or may be stored frozen in liquid nitrogen or at −70° for several months without significant loss of labeling potential. As with the standard nuclease protection assay format, hybridization between probe and target sequences occurs entirely in solution and for that reason constitutes a very quantitative assay.

6.5 Synthesis of cDNA

The synthesis of complementary DNA (cDNA) is an enzymatic, *in vitro* method by which RNA (usually mRNA) is converted stepwise into single- or double-stranded cDNA. First-strand cDNA is synthesized directly from naturally occurring mRNA templates by an enzyme known as *reverse transcriptase*. Thus, the synthesis of cDNA is dependent on the integrity of the mRNA template and precisely complementary to it. Because nucleic acids are only synthesized 5′ → 3′, a primer must be provided, which is complementary to sequences near or at the 3′ end of the RNA template in order to support reverse transcriptase-mediated nucleic acid synthesis. The second strand cDNA can be synthesized only if the original RNA is removed from the RNA:cDNA hybrid. This may be accomplished using older chemical methods (incubation at alkaline pH), enzymatically through the combined activities of RNase H and DNA polymerase I, or by RT-PCR (below).

As a consequence of the very labile character of RNA, the synthesis of stable, double-stranded cDNA is a very important method for amplification of sequences and their long-term storage. Only those transcribed RNAs, which are purified from the cell can be converted into cDNA. Different tissues, even from the same biological source, will yield different cDNA products; as such, cDNA is best thought of as a permanent biochemical record of the cell. cDNA is a means by which the cellular biochemistry can be studied in great detail over a period of months or years, much longer than the storage life of RNA in purified form. An in-depth discussion of the mechanics of cDNA synthesis and cloning is found elsewhere in this volume.

6.6 RT-PCR

The polymerase chain reaction (PCR) is a primer-mediated, enzymatic method for the quasiexponential amplification of nucleic acid sequences. This revolutionary method exploits the natural 5′ → 3′ polymerase activity of various thermostable DNA polymerase, among which *Taq* DNA polymerase is the quintessential example. Two short oligonucleotides function as nucleic primer sequences; their orientation facing each other supports the enzymatic amplification of that sequence, which lies between (is framed by) their respective 5′ ends.

RT-PCR is a twofold process. First, high-quality RNA must be converted to first-strand cDNA by reverse transcription. The components and mechanics of this reaction are nearly identical to any other first-strand cDNA synthesis reaction. Second, the products of the first strand synthesis reaction are diluted in buffer, which provides all of the cofactors necessary to support amplification of these products by PCR (Newer methods for performing RT-PCR require only one enzyme in a single reaction tube format (one-tube RT-PCR)). The resulting cDNA synthesis products are thus amplified as would be DNA from any other source. This approach is predicated upon the availability of an appropriate set of primers. PCR-amplified cDNA products can then be cloned, subcloned, and otherwise manipulated or quantified in order to characterize some aspect of the cellular biochemistry. In addition to its obvious utility for the quantification of gene expression, the judicious design of primers permits RT-PCR to be used to map the 5′ and 3′ ends of transcripts (5′ RACE and 3′ RACE, respectively), detect alternative splicing of transcripts, and identify induced and repressed genes under a defined set of environmental conditions (subtraction–suppression PCR).

6.7 RNAi

A remarkable new tool has emerged that is able to suppress expression of specific endogenous genes through the use of double-stranded RNA (dsRNA). In the few short years since the demonstration of the power of this technique in *Caenorhabditis elegans* and subsequently in human and other mammalian cells, refinements in the methodology have had the same level of impact on research that PCR proffered. This new and emerging technology, known as *RNA interference* (RNAi). RNA interference is a patented process. Commercial use this process may require licensing form the Carnegie Institution of Washington. For information contact the Director of Administration and Finance, Carnegie Institution of Washington, 1530 P Street, N.W., Washington, DC 20005. Telephone: 202-939-1118. RNAi is also frequently referred to as *gene knockdown* or *posttranscriptional gene silencing*.

RNAi is a natural phenomenon that was considered an oddity when it was first observed in petunias. It is now known to exist in many organisms as a means of protecting against viruses and other molecular invaders that would otherwise plague a host genome and wreak havoc. This method of protecting the integrity of the eukaryotic genome is highly evolutionarily conserved, and dsRNA entering the cell is targeted for immediate destruction. Natural processes mediated by RNAi certainly include the turnover of both wild-type and mutant mRNAs and translational regulation during the development of an organism, and undoubtedly other regulatory mechanisms in the cell that have not yet come to light.

RNAi is an endogenous catalytic pathway that is triggered by dsRNA. The ''trigger'' can occur naturally, as in the case of a cellular infection by a dsRNA virus, or by the intentional introduction of dsRNA to induce user-directed degradation of the homologous transcript(s). The net result of RNAi is the downregulation of specific genes by destruction of their mRNA(s). This method of studying the effects of gene expression in a cell or in an organism is occasionally loosely referred to as *reverse genetics*, the goal of which is to determine the consequences for a cell when a protein

is *not* produced. This has profound ramifications in the realm of developmental biology, the treatment of infectious diseases, and other diseases that result from inappropriate protein expression (gain-of-function mutations). The major strength of RNAi is that it permits the study of the function of one gene at a time, and does so over an extended period.

RNAi has emerged as an important mainstream tool for both basic and applied research, and as already revolutionized what has become known as *functional genomics*. RNAi is ubiquitous in eukaryotes and currently is the preferred tool for investigating the regulation of gene expression in plants, animals, and fungi. This method is becoming increasingly popular because of its wide-ranging applicability in research owing to its compatibility with cell culture as well as *in vivo* models. Comparatively speaking, RNAi is much faster and much more economical than creating knockout animals in order to study the function of specific genes. The resulting precision silencing of specific genes also makes RNAi an attractive platform for the discovery and development of life-saving pharmaceuticals. There are multiple approaches by which RNAi can be induced, each of which has several mechanistic permutations. RNAi is, fundamentally, a two-step process (Fig. 5). The first step involves one of the master enzymes in the RNAi process, a type III endoribonuclease aptly named *Dicer*. This enzyme, a ubiquitous member of the eukaryotic proteome, is involved in the digestion of long dsRNA into 21- to 23-bp short inhibitory RNA (siRNA) molecules with characteristic 3′ dinucleotide overhangs on both strands. In addition, the siRNA manifest a 5′-phosphate and a 3′-OH terminus. The long dsRNA can be introduced

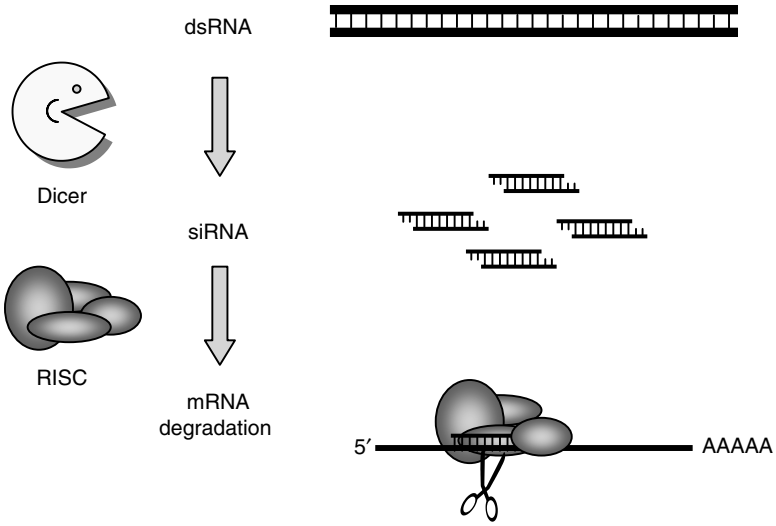

Fig. 5 Major steps in the RNAi process. dsRNA from any of a number of sources and in any of a number of configurations is cut by the enzyme Dicer into siRNA, which, in turn, become part of the multicomponent RISC. This ultimately leads to destruction of the target mRNA and concomitant downregulation of the associated gene. (From Farrell Jr., R.E. (2005) *RNA Methodologies: A Laboratory Guide for Isolation and Characterization*, 3rd edn., p. 607.) With permission from Elsevier.

into the cell where it will become a substrate for Dicer; otherwise, recombinant Dicer can be used to generate siRNA *in* vitro, after which these short molecules are introduced into the cell by transfection. In the second step, siRNA, regardless of the source, becomes part of a multicomponent nuclease-containing RNA-induced silencing complex (RISC). Part of RISC is an ATP-dependent helicase that unwinds the double-stranded siRNA, the antisense component of which is now able to base pair with the mRNA to be silenced. The formation of a double-stranded region between the antisense component of the silencing RNA and the cognate mRNA dooms it. RISC cuts the mRNA close to the middle of this transiently formed double-stranded region. The mRNA is then further degraded, preventing any level of interaction with the cellular translation machinery. The subtleties of RNAi are described in much greater detail elsewhere in this volume.

6.8 *In Vitro* Translation

The classical methods for the analysis of RNA include all of the standard techniques described above and many others. Another aspect of the RNA story, however, is the destiny of those transcripts, which emerge as mature mRNA molecules in the cytoplasm. mRNA biogenesis guarantees neither translation nor translatability; a gene is really not ''expressed'' until a functional peptide is produced. In order to more fully characterize gene expression, the extent of translation may be assessed by Western analysis, and the resulting data correlated to the transcriptional activity of the corresponding gene(s).

The translation of RNA into protein *in vitro* goes hand in hand with message quantification as a parameter of gene expression. Briefly, naturally synthesized mRNA or message synthesized by *in vitro* transcription is added to a whole cell lysate containing all of the components needed to support the *in vitro* translational of mRNAs added to the system. Common *in vitro* translation systems include the reticulocyte lysate system and the wheat germ extract system, and, in some cases, microinjection of message directly into a living cell. Pretreatment of the *in vitro* translation system lysates with micrococcal nuclease destroys endogenous mRNA, ensuring that the synthesis of *de novo* protein products harvested from the system was supported exclusively by the introduction of experimental mRNA. The same *in vivo* requirements for 5′ cap, initiation codon, and polyadenylation apply here if experimental introduced message is to be translated with any efficiency at all. Protein products are then analyzed as usual by Western analysis, biological assay, immunopurification, and so forth. This particular aspect of biotechnology is an attractive technique in a number of different applications, including the study of naturally occurring animal and plant mRNAs, transfection experiments, characterization of mRNA products, protein engineering, screening and analysis of mutants, and DNA, RNA, or protein-binding studies.

7 Summary

The characterization of ribonucleic acid (RNA) from biological sources is a central act of profound significance in molecular biology. Gene expression is frequently analyzed by blot analysis, by solution hybridization methods such as nuclease protection assay, and by the synthesis and

study of cDNA by RT-PCR. More and more, many of these classical methods are becoming streamlined or even circumvented by utilization/exploitation of the polymerase chain reaction. While no one would argue against the fact that PCR has revolutionized many aspects of biotechnology, it is important to realize that PCR is not a reason, but a tool used to achieve an end. In the absence of a clear understanding of experimental goals and, certainly, without high quality RNA as starting material, data intended to reflect the cellular biochemistry and provide insight into gene regulation are hardly reliable.

Keywords

Base Pair
Base pairs are formed by specific hydrogen bonds between two nucleobases. The canonical Watson–Crick pairs between guanosine and cytosine (GC), and between adenosine and uracil (AU), as well as the wobble pairs between guanosine and uracil (GU) regularly appear in RNA structures. The nucleobases of the two paired nucleotides form a planar structure.

Dynamic Programming
A general computational technique that is based on solving a combinatorial optimization problem recursively, while tabulating intermediate results. In the case of RNA folding, this means composing large structures from the foldings of shorter subsequences.

Helix or Stem
Helices or stems are formed by stacking base pairs on top of each other. The interaction of the parallel planar arrangements of the nucleobases stabilizes the three-dimensional structure. The geometry of helices is nearly sequence independent, as long as they contain only canonical base pairs, whence energy contributions of stacked pairs are nearly independent of each other.

Loops
Loops are formed by those parts of the molecule that are not part of a helix. Different types of loops (bulges, interior loops, and multibranch loops) can be distinguished depending on their structure. Loops destabilize the structure. In the context of RNA folding algorithms, one considers adjacent stacked pairs as a special type of (stabilizing) loop. In this language, each secondary structure can be decomposed completely into loops, which form the basis of the empirical energy model.

Noncoding RNA
An RNA molecule with any function other than encoding proteins.

Pseudoknot
A structural feature composed of crossing base pairs. Pseudoknots are in most cases excluded from computational approaches for technical reasons.

RNomics
The emerging science of RNA molecules and their interactions in the cell.

Secondary Structure
The secondary structure is the collection of *base pairs* or, equivalently, of *loops* and *helices*. In a stricter sense, secondary structures are defined as crossing-free collections of base pairs. All other base pairs are then considered as part of a higher-order (tertiary) structure.

The three-dimensional structures of nucleic acids, RNA, and DNA, are dominated by double-helical regions that are formed by canonical Watson–Crick and wobble (GU) base pairs, which collectively are referred to as the *secondary structure of the molecule*. In the case of RNA, this level of description is of particular interest because it captures the thermodynamics of RNA folding quite well and allows a self-consistent description of folding dynamics. Furthermore, secondary structures are often evolutionarily well conserved, evolving much slower than the underlying sequences. From a bioinformatics perspective, RNA secondary structures are a convenient representation because efficient exact algorithms are known to enumerate the structures that can be formed by a given sequence, to solve the folding problem, and to compute the partition function (and hence any thermodynamic quantity of interest) from a well-measured set of empirical energy parameters.

1 Introduction

Secondary structures, that is, patterns of base pairing, not only form the most important distinguishing characteristics of the various classes of RNA molecules but they also provide us with a unique coarse-grained level of description that naturally lends itself to computational studies of RNA structure and evolution.

RNA has moved from a fringe existence to the center stage of research in molecular biology following the discovery of novel classes of small regulatory RNAs. While textbooks still speak of *genes and their encoded protein products*, thousands of human genes produce transcripts that exert their function without ever producing proteins. The list of functional noncoding RNAs (ncRNAs) includes key players in the biochemistry of the cell. Many of them have characteristic secondary structures that are highly conserved in evolution. Databases (referenced in the Table 1) collect the most important classes.

In addition, there is a diverse and growing list of ncRNAs with sometimes enigmatic function. We give just a few examples: The 17-kb *Xist* RNA of humans and the smaller roX RNAs of Drosophila play a key role in dosage compensation and X-chromosome inactivation. Several large ncRNAs are expressed from imprinted regions. Many of these are cis-antisense RNAs that overlap coding genes on the other genomic strand. An RNA (meiRNA) regulates the onset of meiosis in fission yeast. Human vaults are cytoplasmic ribonucleoprotein particles believed to be involved in multidrug resistance. The complex contains several small untranslated RNA molecules. No precise function is known at present for the human H19 transcript, the hrsω transcript induced by heat shock in Drosophila, or the *Escherichia coli* 6S RNA.

Even though the sequence of the human DNA is known by now, the contents of about half of it remains unknown. The diversity of sequences, sizes, structures, and functions of the known ncRNAs strongly suggests that we have seen only a small fraction of the functional RNAs. Most of the ncRNAs are small, they do not have translated ORFs, and they are not polyadenylated. Unlike protein-coding genes, ncRNA gene sequences do

Tab. 1 Major classes of functional RNAs

Type	*Size*	*Organisms*	*Function* –
miRNA	22	Multicellular?	RNA interference
tRNA	70–80	All	Transfer RNA
rRNA 5S	130	All	Part of ribosome
RNase P	260–360	All	tRNA maturation
tmRNA	300–400	Bacteria	Tags protein for proteolysis
snRNA	50–300	Eukaryotes	Part of spliceosome
snoRNA	80–600	Eukaryotes Archea	RNA modification
SRP RNA	300–400	All	Signal recognition particle
rRNA 16S	1500	All	Part of ribosome
rRNA 23S	3300	All	Part of ribosome

not seem to exhibit a strong common statistical signal; hence, a reliable general-purpose computational genefinder for ncRNA genes has been elusive. It is quite likely therefore that a large class of genes has gone relatively undetected so far because they do not encode proteins.

Another level of RNA function is presented by functional motifs within protein-coding RNAs. We list a few of the best-understood examples of structurally conserved RNA motifs in viral RNAs:

- An *IRES* (internal ribosomal entry site) region is used instead of a CAP to initialize translation by Picornaviridae, some Flaviviridae including Hepatitis C virus, and a small number of mRNAs.
- The TAR hairpin structure in HIV and related retroviruses is the target for viral transactivation.
- The RRE structure of retroviruses serves as a binding site for the Rev protein and is essential for the viral replication. The RRE is a characteristic five-fingered structural motif.
- The CRE hairpin in Picornaviridae is vital for replication.

A textbook example of a functional RNA secondary structure is the *Rho*-independent termination in *E. coli*. The newly synthesized mRNA forms a hairpin in the 3′UTR that interacts with the RNA polymerase causing a change in conformation and the subsequent dissociation of the enzyme–DNA–RNA complex.

Only part of the mature mRNA is translated into protein. At the 5′ terminus of the mRNA, just behind the cap, is a noncoding sequence, the so-called leader sequence (10–200 nt) that may be followed by another noncoding sequence of up to 600 nt. An increasing number of functional features in the untranslated regions of eukaryotic mRNA have been reported in recent years.

An extreme example is the Early Noduline gene. Enod40, which is expressed in the nodule primordium developing in the root cortex of leguminous plants after infection by symbiotic bacteria, codes for an RNA of about 700 nt that gives rise to two short peptides of 13 and 27 amino acids, respectively. The RNA structure itself exhibits significant conservation of secondary structure motifs, and might take part in localization of mRNA translation,

as in the case of the bicoid gene *bcd* of Drosophila.

2 Basic Concepts

2.1 Representations of Secondary Structures

A *secondary structure* Ψ is a special type of contact structure, represented by a list of base pairs (i, j) with $i < j$ on a sequence x, such that for any two base pairs $[i, j]$ and $[k, l]$ with $i \leq k$ holds:

1. $i = k$ if and only if $j = l$, and
2. $k < j$ implies $i < k < l < j$.

The first condition simply means that each nucleotide can take part in at most one base pair. The second condition forbids knots and pseudoknots. While pseudoknots are important in many natural RNAs, they can be considered part of the tertiary structure for our purposes. We will therefore neglect them for the most part of this presentation. The restriction to knot-free structures is necessary for the efficient dynamic programming algorithms discussed below.

The two conditions above imply that secondary structures form a special type of graph. In particular, a secondary structure graph is *subcubic* (i.e. the vertex degree is at most three) and *outer-planar*. The latter property means that the structure can be drawn in the plane in such a way that all vertices (which represent the nucleotides) are arranged on a circle (the molecule's backbone), and all edges (which represent the bases pairs) lie inside the circle and do not intersect, see Fig. 1.

Secondary structures can also be stored compactly in strings consisting of dots and matching brackets: For any pair between positions i and j ($i < j$) we place an open bracket "(" at position i and a closed bracket ")" at j, while unpaired positions in the molecule are represented by a dot ("."), see Fig. 1c. Since base pairs may not cross, the representation is unambiguous.

Although secondary structure graphs are always planar, it is not trivial to find nonoverlapping and visually pleasing layouts for large structures. A representation that works well for large structures and is well suited for comparing structures is the so-called mountain representation. In the mountain representation, a single secondary structure is represented in a two-dimensional graph, in which the x-coordinate is the position k of a nucleotide in the sequence and the y-coordinate is the number $m(k)$ of base pairs that enclose nucleotide k.

Often it is desirable to present not just one structure, but an ensemble of structural possibilities. Mountain plots can be adapted for structural ensembles by using the *mean* number of base pairs $m(k)$. A more detailed representation is given by so-called dot plots, where each possible pair (i, j) is represented by a dot on square grid. The size or color of the dot is used to indicate the probability p_{ij} of the pair, or the best possible energy of a structure containing this pair. Dot plots can provide an excellent overview of possible alternative foldings. Fig. 4 gives examples of dot plots and mountain plots.

2.2 Combinatorics and Typical Structures

The basic studies into the combinatorics of RNA secondary structures goes back to the work of M. Waterman in the late 1970s.

We begin our exposition by counting the secondary structures that can be formed by a given sequence $x = (x_1, x_2, \ldots, x_n)$

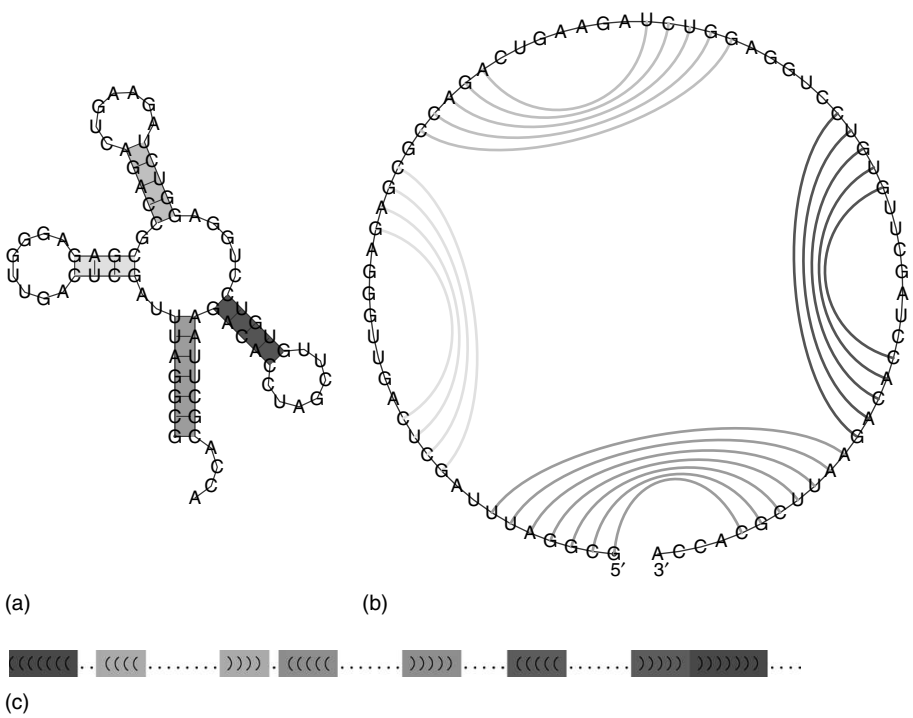

Fig. 1 Secondary structure of phenylalanine-tRNA from yeast as (a) conventional drawing, (b) in circular representation, and (c) in dot-bracket notation. Colors are used to highlight pairs belonging to the same helix. Note that the chords in the circular representation must not cross in secondary structure graphs. (See color plate p. xl).

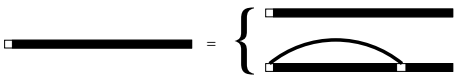
of length n. We will simply write "(i, j) pairs" to mean that the nucleotides x_i and x_j *can* form a Watson–Crick or a wobble pair, that is, $x_i x_j$ is one of **GC**, **CG**, **AU**, **UA**, **GU**, or **UG**. The basic idea behind all dynamic programming algorithms for RNA folding is the observation that a structure on n nucleotides can be formed in only two distinct ways from shorter structures: Either a structure on $n-1$ nucleotides is extended by an unpaired base, or the nth nucleotide is paired. In the latter case, it has a pairing partner, say j such that the (j, n) pair encloses a secondary structure on the subsequence from $j+1$ to $n-1$ since base pairs must not cross by definition. The remainder, the interval from 1 to $j-1$ is of course also a secondary structure:



It is now easy to compute the number N_{ij} of secondary structures on the subsequence $x[i..j]$ from positions i to j:

$$N_{ij} = N_{i+1,j} + \sum_{k,(i,k)\text{pairs}} N_{i+1,k-1} N_{k+1,j} \tag{1}$$

The first term accounts for the case in which position i is unpaired, the

terms in the sum consider the base pairs from i to some position k. Because of the "no-pseudoknots" condition, both the part of the sequence that is enclosed by the pair (i, k) and the part beyond the base pair form secondary structures that are completely independent of each other: thus, we may simply multiply their numbers.

The counting recursion can also be used to produce uniformly distributed random structures, or adapted to derive typical structural features of RNA molecules such as expected helix length or distribution of loop types. One should note, however, that such random structures differ significantly from the typical structures obtained from folding random or natural sequences. In contrast to folded structures, random structures contain many loops connected by short helices or even isolated base pairs. Qualitative features, such as an average length of helical regions independent of the sequence lengths or the distribution of branching orders of loops is shared between random and biological structures.

2.3 Energy Model

The physicochemical basis for the coarse-grained secondary structure model is the fact that a dominating part of the energy of structure formation is contained in the stacking of the aromatic nucleobases that gives rise to helical base-paired regions with a spatial structure that can be considered as almost sequence independent. This distinction between paired and unpaired regions allows us to approximate the free energy of structure formation given the sequence and the list of base pairs. It is important to note that a secondary structure as defined in the previous section corresponds to an *ensemble* of conformations of the molecule at atomic resolution restricted to a certain base pairing (hydrogen bonding) pattern. For example, no information is assumed about the spatial conformation of unpaired regions. The entropic contributions of these restricted conformations have to be taken into account, and hence we are dealing with (temperature dependent) free energies.

This free energy of an RNA secondary structure is assumed to be the sum of the energy contributions of all "loops," that is, the faces of the planar drawing of the structure. This decomposition has a solid graph theoretical foundation: the loops form the unique minimal cycle basis of the secondary structure graph. More importantly, however, a large number of careful melting experiments have shown that the energy of structure formation (relative to the random coil state) is indeed additive to a good approximation. Usually, only Watson–Crick (**AU**, **UA**, **CG**, and **GC**) and wobble pairs (**GU**, **UG**) are allowed in computational approaches since nonstandard base pairs have, in general, context-dependent energy contributions that do not fit into the "nearest-neighbor model". Individual nonstandard base pairs are therefore treated as special types of interior loops in the most recent parameter sets.

Qualitatively, there are two major energy contributions: stacking of base pairs and loop entropies. Stacking energies can be computed for molecules in the vacuum by means of standard quantum chemistry approaches. The secondary structure model, however, considers only energy differences between folded and unfolded states in an aqueous solution with rather high salt concentrations. As a consequence, one has to rely on empirical energy parameters. Loops are destabilizing: the closing base pair restricts the possible conformations

of the sequence in the loop relative to the conformations that could be formed by the same sequence segments in a random coil, resulting in an entropy loss and thus an increase in free energy.

A collection of energy parameters is maintained by the group of David Turner. These standard parameters are measured in a buffer of 1 M NaCl at 37 °C. Since both entropies and enthalpies are available, the parameters can be extrapolated to other temperatures. As examples we list the free energies for stacked pairs in Table 2. Note that a single additional base pair can stabilize a structure by up to −3.4 kcal mol^{-1}.

2.4 Pseudoknotted Structure

The definition of secondary structure relegates pseudoknots to the realm of a tertiary structure. Often this is justified purely by convenience, since the simple dynamic programming algorithms, which will be described in some detail in the following section, cannot handle pseudoknotted structures. It is worth mentioning, however, that many pseudoknotted base pairing patterns are not sterically feasible, while any knot-free secondary structure can be realized in 3D.

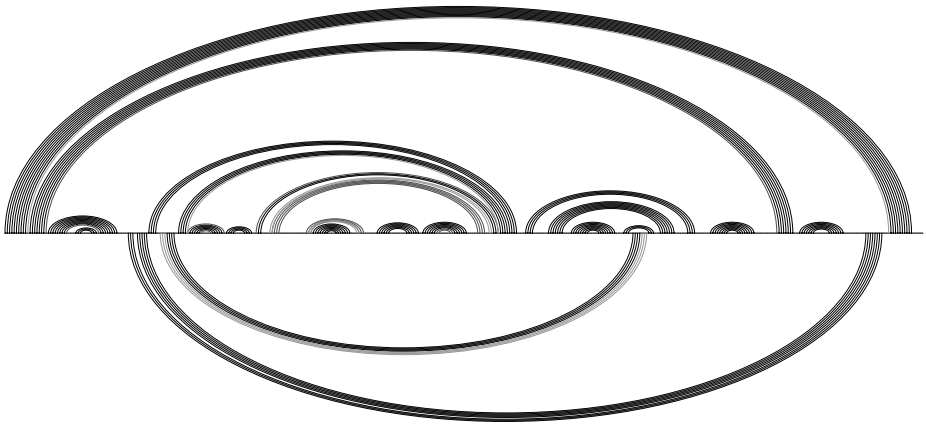

Fig. 3 Bisecondary structure of RNase P RNA as predicted by HXMATCH compared to the reference structure. Black: correct predicted base pairs; green: base pairs not predicted; red: predicted pairs not present in reference structure (See color plate p. xxxix).

Comparative sequence analysis revealed conserved pseudoknots in many important classes of RNA, such as rRNAs, RNase P RNAs, and tmRNA. Consequently, there is significant interest in computational methods for their prediction. While thermodynamic structure prediction with a loop-based energy model is NP-complete, in general, restricted classes of pseudoknots can be dealt with by polynomial algorithms (Fig. 2). Fortunately, most known pseudoknots are relatively simple. With few exceptions, they can be drawn as a superposition of just two knot-free secondary structures, that is, as a bisecondary structure. Recently a number of polynomial time algorithms have been proposed that predict pseudoknotted structures. Depending on how restrictive the set of allowed pseudoknots is chosen, their time complexity ranges between $\mathcal{O}(n^6)$ and $\mathcal{O}(n^4)$.

The practical applicability of these algorithms, however, is limited not only by their time and memory requirements, but most severely by our poor knowledge of pseudoknot energetics. Useful energy parameters have so far only been collected for simple H-type pseudoknots. In the absence of good scoring functions, expanding the set of possible structures will often lead to predictions that are worse than knot-free predictions.

The problem can be somewhat mitigated in methods that work with multiple sequence and exploit the covariance information in an alignment, such as ILM and HXMATCH. An example is shown in Fig. 3.

3 RNA Structure Prediction

3.1 Structure Prediction by Energy Minimization

Given an energy model the simplest approach to structure prediction is to determine the optimal structure with respect to its free energy, that is, the minimum free energy (MFE) structure. For pseudoknot free RNA secondary structures, the optimal structure can

be computed efficiently using dynamic programming.

If the energy of a structure could be modeled as a sum of contributions from base pairs, an optimal structure could be computed from a simple variant of the counting recursion 1,

$$E_{ij} = \min\{E_{i+1,j} + \min_{k,\,(i,k)\ \text{pairs}} \times \{E_{i+1,k-1} + E_{k+1,j} + \beta_{ik}\}\}, \quad (2)$$

where β_{ik} is the energy contribution of a pair between positions i and k. The algorithm requires $\mathcal{O}(n^2)$ memory for storing the E matrix while cpu timescales as $\mathcal{O}(n^3)$. While this was the first approach to structure prediction used by Nussinov, a loop-based energy model as described above is necessary to obtain reasonable accuracies. Using a loop-based energy model requires somewhat more involved recursions, but still exhibits the same time and space complexity.

As is typical for dynamic programming, the algorithm first computes the best possible energy of a secondary structure, then ''backtracks'' to find a structure with this optimal energy. In the simplest case, this procedure returns a single solution, the MFE structure. This is unsatisfactory not only because inaccuracies in the energy parameters will lead to errors in the predicted structure but also because significantly different structures may be needed to represent the molecule in thermodynamic equilibrium.

3.2 Suboptimal Folding and Pair Probabilities

The most common strategy for generating additional suboptimal structures is the algorithm Michael Zuker, which considers for each possible base pair the best structure containing that pair. The number of structures in the output is further reduced by considering only structures within some energy interval of the mfe and filtering out structures that are too similar to others. The method usually returns a short list of possible foldings that form a representative sample. Occasionally, however, important alternatives will be missed.

A more rigorous approach is the computation of the partition function and base pairing probabilities using McCaskill's algorithm. For every possible base pair (i, j), the algorithm yields the probability p_{ij} that the base pair will be formed, that is, the sum of the probabilities of all structures containing that pair. The partition function can also be used to calculate heat capacities and thus characterize melting transitions.

Base pair probabilities can be nicely represented in dot plots, where we plot a square with area p_{ij} for each pair (i, j). Similarly, Zuker's suboptimal folding algorithm can produce energy dot plots, where instead of the probability, the best possible energy in structures containing (i, j) is plotted.

The *complete* suboptimal folding algorithm of Wuchty et al. can generate *all* suboptimal structures in a predefined energy range above the mfe. For small molecules, it can be illuminating to look at the exhaustive list of structural possibilities. For larger molecules, the information quickly becomes overwhelming. With further postprocessing, however, these data can be used for detailed analysis of RNA energy landscapes and the dynamics of the folding process.

Finally, the partition function algorithm can be enhanced with a stochastic backtracking procedure, which samples suboptimal structures from the Boltzmann distribution. This can be used to compute the average value of any structural feature

simply by sampling a sufficiently large number of suboptimal structures.

3.2.1 Available Programs and Web Services

Zuker's suboptimal folding algorithm is implemented in his popular `mfold` program for UNIX, as well as in David Mathew's `RNAstructure` for Windows. Partition function folding, complete suboptimal folding, and stochastic backtracking are all available as part of the `Vienna RNA Package`.

Users who need to do structure predictions only occasionally will find several of the above algorithms as a Web service on Michael Zuker's mfold server at http://bioinfo.math.rpi.edu/~zuker/rna/, as well as the Vienna RNA server http://rna.tbi.univie.ac.at.

3.2.2 Prediction Accuracy

Prediction accuracies can be evaluated by comparison to structures inferred using phylogenetic methods (see the following). For short RNAs such as tRNAs, one can expect accuracies (in terms of known base pairs that are correctly predicted) of around 70%. As pointed out recently by Doshi et al., long-range pairs are generally predicted poorly, resulting in a mean accuracy of only 41% for the large 16S and 23S rRNAs. While predicted mfe structure may have less then 20% correct pairs in unfortunate cases, good structures are still found in the vicinity of the mfe structure by suboptimal folding. Moreover, even when overall prediction accuracy is low, pairs that are predicted with high probability are usually correct.

Often a small number of constraints can dramatically improve prediction accuracy. Most folding programs allow constraints, such as specifying positions as (un)paired, to be specified. Such constraints can be obtained without too much effort from chemical probing experiments.

3.3 Well-defined Regions and Reliability

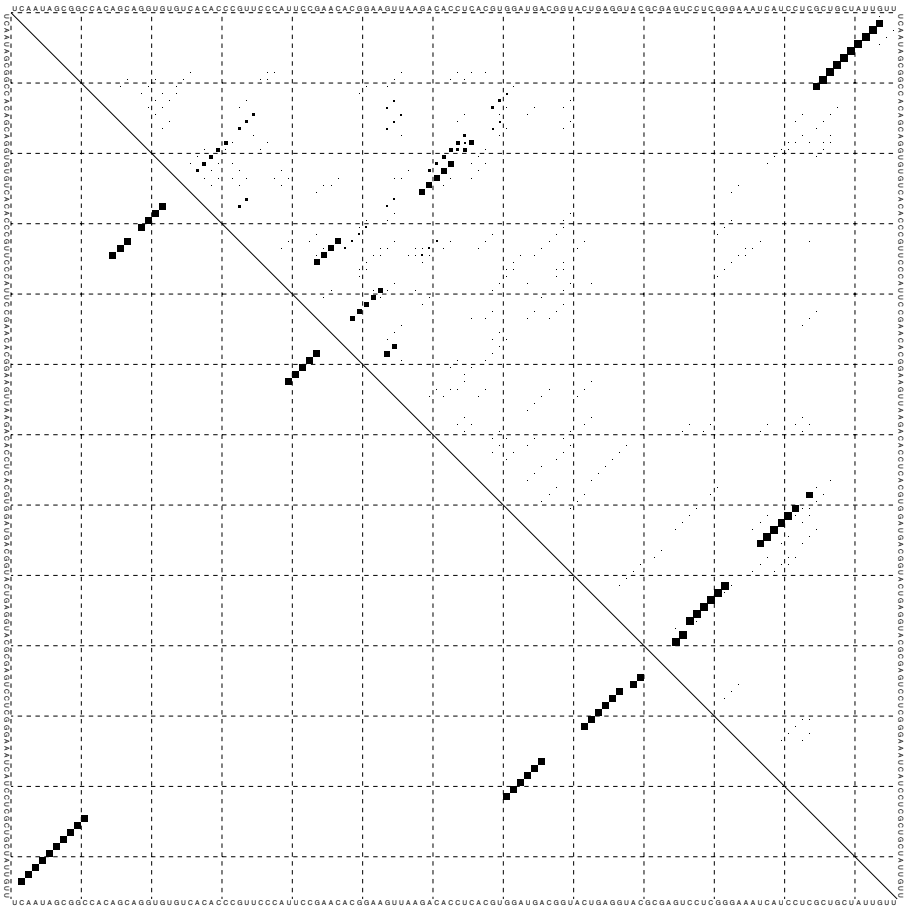
Pair probability and energy dot plots can also give a good visual impression of the quality of prediction and well-defined regions. A dot plot cluttered by many alternatives may not only indicate structural flexibility but may also make the prediction of a single mfe structure less reliable. Well-defined structures are likely to be correctly predicted, since they will be robust with respect to small variations of the energy parameters.

Several quantitative measures of well definedness are being used. In the simplest case, the well definedness of the prediction can be quantified by the difference between the MFE and the free energy of the best suboptimal structure. A more robust measure is the difference between the mfe and the ensemble free energy $G = -RT\ln(Q)$ where Q is the partition function. The latter is equivalent to the probability of the mfe structure in the ensemble given by Boltzmann's law $p(mfe) = \exp(-E_{\min}/RT)/Q = \exp(-(E_{\min} - G)/RT)$.

Even more useful are position-wise measures that help identify credible parts of the prediction. One can, for example, compute from the pair probabilities p_{ik} the positional entropy

$$S_k = -\sum_i p_{ik} \ln p_{ik} \qquad (3)$$

where p_{ii} is defined as the probability that i does not pair $p_{ii} = 1 - \sum_{j \neq i} p_{ij}$. A useful application of this measures is the annotation of structure drawings (Fig. 4).



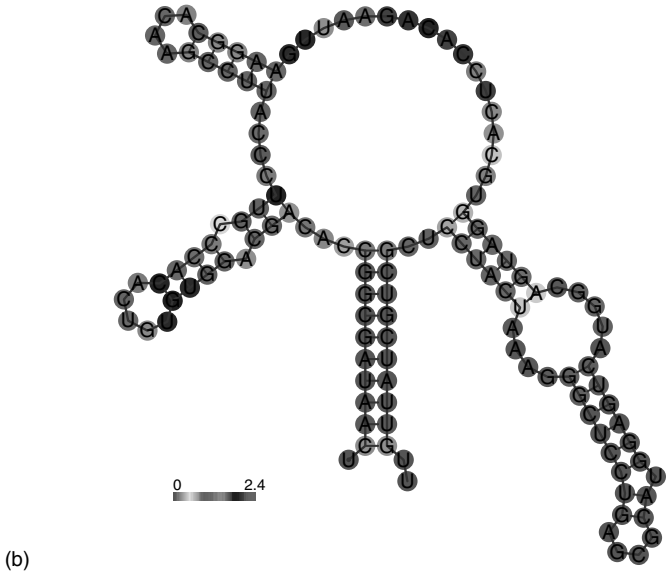
(a)

Fig. 4 Predicted structure for an 5S rRNA. (a) base pair probabilities as computed by `RNAfold -p -noLP`; (b) predicted mfe structure annotated with positional entropy; (c) Mountain plot. Note that all regions with low entropy (red) are correctly predicted, while high entropy regions (blue) deviate from the reference structure (See color plate p. xli).

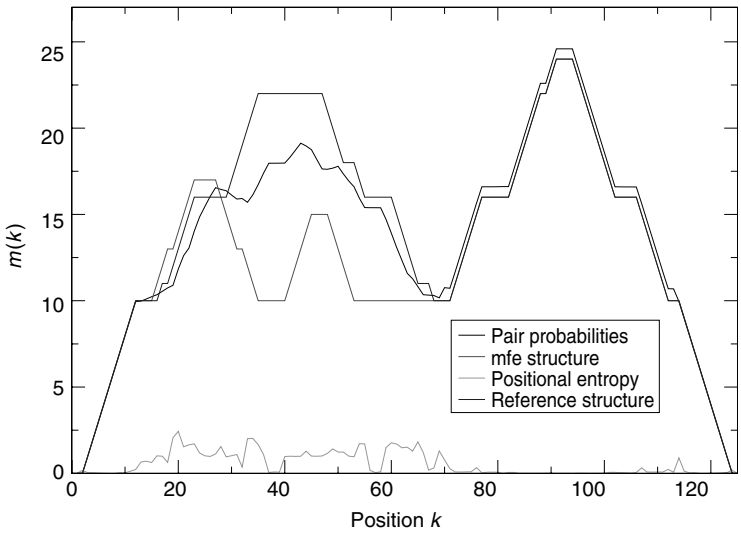
3.4 Structure Prediction using Sequence Covariation

If several sequences are known to fold into (almost) the same structure, their common structure can be inferred from sequence covariation, typically measured as mutual information between two columns of a multiple sequence alignment. The approach requires a large number of related sequences and has therefore been mostly limited to ribosomal RNAs and tRNAs. However, where applicable, these phylogenetic methods produce secondary structure models of high quality, and can even elucidate some tertiary interactions.

Recently, a number of methods have appeared that combine thermodynamic prediction with covariation analysis, in order to achieve accurate predictions with only a few related sequences. Usually, these



(b)



(c)

Fig. 4 (*Continued*)

methods start from a conventional multiple sequence alignment. One approach, as exemplified by the `alidot` and `ConStruct` tools, is to predict structures of individual sequences, combine them using the sequence alignment, and then find significantly conserved structure motifs. This is particularly useful when searching for locally conserved structure motifs in larger sequences.

Another approach that is suitable for predicting globally conserved structures

works by modifying the folding algorithm itself so that an optimal structure is predicted for a sequence profile, or a multiple sequence alignment, instead of a single sequence. The two best-known implementations of this approach are `pfold` and `RNAalifold`. `pfold` is based on a stochastic context-free grammar, and thus uses parameters derived from a training set; it also makes explicit use of a predicted phylogenetic tree. `RNAalifold`, on the other hand, uses the standard energy model for RNA secondary structures, augmented with a covariation term that rewards consistent and compensatory mutations. Thus, for identical sequences, it gives the same result as the single sequence prediction from `RNAfold`. With a few (or even just two) related sequences, these programs achieve prediction accuracies much higher than prediction methods for single sequences.

Methods starting from a multiple sequence alignment are of course limited by the accuracy of the input alignment. Typically, this becomes a problem when pairwise sequence identities drop below 60%. An alternative is to start by aligning predicted mfe structures using `RNAforester` or `MARNA`. The most rigorous way is to use a variant of the Sankoff algorithm, which computes the alignment and consensus structure simultaneously. Notable implementations are `foldalign`, `dynalign`, `pmcomp/pmmulti`, and `dart`. The Sankoff algorithm is, however, computationally very expensive ($\mathcal{O}(n^6)$ in the unrestricted case). The above algorithms therefore use various restrictions to improve speed.

3.4.1 Search for ncRNA

With the realization that a significant fraction of the genomic DNA of higher organisms might code for functional RNAs rather than protein-coding genes, the development of techniques for the detection and classification of RNAs in large sequences has become an active field of research. Generally, we can distinguish between experimental and computational methods to search for ncRNA. Experimental methods, as ligation of 5′ and 3′ adapters to size fractionated isolated RNA, followed by reverse transcription, cDNA cloning and sequencing, or simply using Northern blot analysis for sequence-specific detection of ncRNAs are at present restricted to the detection of abundant ncRNA. In this chapter, we will therefore concentrate on computational methods.

Some ncRNAs can be found by searching for likely transcripts that do not contain an open reading frame. A survey of the *E. coli* genome for DNA regions that contain a $\sigma 70$ promotor within a short distance of a *Rho*-independent terminator, for instance, resulted in 144 novel possible ncRNAs. This approach is limited, however, to functional RNAs that are transcribed in the ''usual'' manner by means of pol-II. For many ncRNAs, however, the mode of transcription is unknown.

Neural networks or support vector machines have also been successfully trained to recognize all known ncRNA in the *E. coli* genome. The survey conducted resulted in 370 new candidates, which have not been verified experimentally. The number seems to be quite reasonable, in particular when we keep in mind that false positives are a common problem with most computational searches for ncRNA so far.

Some structure-based searches use the known secondary structure of the major classes of functional RNAs. Programs such as `RNAmot`, `tRNAscan`, `HyPa`, `RNAMotif`, `bruce`, and many others exploit this

avenue. An interesting variant that makes use of evolutionary computation is described by Fogel. Nevertheless, all these approaches are restricted to searching for new members of the few well-established families. Especially for miRNAs, being quite short with a characteristic stem-loop structure ending up in a hairpin, several genome-wide surveys have been undertaken. The initially very large number of candidates is filtered in a postprocessing process according to other structural and sequential elements.

Comparative approaches such as the program `QRNA` can detect novel structural RNA genes in a pair of aligned homologous sequences by deciding whether the substitution pattern fits better with (1) synonymous substitutions, which are expected in protein-coding regions; (2) the compensatory mutations consistent with some base-paired secondary structure; or (3) uncorrelated mutations. Genome-wide scans for new ncRNA have already been accomplished with `QRNA`.

Another approach tries to determine functional RNAs by means of structure prediction. The basic assumption is that functional and hence conserved structures will be thermodynamically more stable. While such procedures are capable of detecting some particularly stable features, a recent study concludes that ''although a distinct, stable secondary structure is undoubtedly important in most noncoding RNAs, the stability of most noncoding RNA secondary structures is not sufficiently different from the predicted stability of a random sequence to be useful as a general genefinding approach.'' Nevertheless, in some special cases such as hyperthermophilic organisms, **GC**-content (and hence thermodynamic stability) proved sufficient.

When thermodynamic stability is combined with comparative methods, structural ncRNAs can indeed be recognized with high specificity and sensitivity. Two such approaches were developed recently building on consensus structure predictions using `RNAalifold`. The `alifoldz` method compares the folding energy of the native alignment with those of randomized alignments, using a somewhat costly shuffling procedure. The even faster `RNAz` method combines a measure for RNA secondary structure conservation on the basis of comparing the consensus folding energies to folding energies of individual sequences, with a measure for thermodynamic stability, which is normalized with respect to both sequence length and base composition. This method is fast and reliable enough to scan even large vertebrate genomes.

4 Current Research in RNA Secondary Structures

Despite the recent progress in detection algorithms for ncRNAs in comparative genomics approaches, a reliable *annotation* of functional RNAs in genomic data is still a largely unsolved problem for a variety of reasons. Most importantly, annotation is almost always limited to comparative methods; at present there are no generally applicable methods that could be used to determine the function of an RNA from its sequence and/or (predicted) structure. So far, structure and function of only a very small fraction of ncRNAs and other functional RNA motifs have been characterized. In fact, the functions of a number of very well conserved, evolutionary ancient ncRNAs such as Y

RNAs or vault RNAs have remained in the dark.

Even the recognition of members of the large classes of known ncRNAs is less straightforward than one might expect: the sequences of snoRNAs, snRNAs, and many others evolve relatively rapidly, their secondary structures are thus the main features that can be used to identify them. Note that it is much easier to identify additional members of a family of homologous snoRNA and microRNAs than to recognize a new class of homologous ncRNAs, for which no member has been described experimentally, as a novel family of microRNAs or snoRNAs. For the first class of problems, simple sequence comparison or general pattern matching techniques that combine sequence and secondary structure information, such as `ERPIN`, `HyPa`, or `PATSearch`, can be used in many cases. While search tools exist for such pattern description languages, the inference of characteristic patterns from a set of aligned (or, even more demanding, nonaligned) sequences is still an open problem.

In the case of microRNAs, a characteristic pattern of mutations in the precursor hairpin is a reliable signal provided a sufficient number of homologous sequences can be found. The motifs of box H/ACA and box C/D snoRNAs, as well as the short sequences for some snRNAs, are less informative, however. In this case, knowledge about their potential targets, rRNAs, snRNAs, and some mRNAs, can be used to improve the quality of the prediction. In the case of snRNAs, conserved promoter and enhancer sequences could potentially be used. However, efficient tools for RNA classes besides tRNAs that could be used in genomic surveys are at present not available.

The identification of the target genes of microRNAs is a hot topic at present. While microRNAs bind their target mRNAs almost complementarily in plants, the mechanism appears to be much more complicated in animals. As a consequence, none of the approaches published to date, such as `miRanda`, `targetscan`, or `RNAhybrid` provide a complete solution to the problem. From an algorithmic point of view, the microRNA target problem has stimulated research into methods for computing RNA–RNA interactions, and to consider RNA–protein interactions in a more systematic way.

A related open problem concerns the classification of the ncRNAs that do *not* belong to one of the known classes. While it is unlikely that the functions of these molecules can be elucidated without further experimental data, it is of interest to determine whether there are additional larger classes of ncRNAs that have escaped our attention. Of course, the same question arises for functional RNA motifs in mRNAs.

Structure-function studies of small RNAs as well as the analysis of artificial RNA sequences obtained from SELEX experiments depend upon the ability to compute structure-based alignments. As mentioned earlier, Sankoff's algorithm solves the RNA folding and pairwise alignment problem simultaneously, but is often computationally too expensive. The alternative, obtaining pairwise alignments through tree editing or tree alignment, is problematic since it depends on predicted, possibly incorrect, structures. In all cases, heuristics are used to obtain multiple alignments from pairwise alignments. Open questions in this area concern both algorithmic improvements and more realistic cost functions; for instance, tree alignments are currently available only with linear gap costs.

RNA structure design can be regarded as the inverse of the RNA folding problem: for a given secondary structure graph, find one or more sequences that have this structure as their MFE structure. An enumeration of sequences that fold into a given structure is infeasible in general because of their large number. A heuristic that turns this problem into a combinatorial optimization problem has already been described. There is, however, no exact algorithm that could determine whether there is at least one sequence that folds into a prescribed secondary structure graph.

RNA switches exhibit two competing conformations, whose equilibrium can be shifted easily by molecular events such as the binding of another molecule. Such elements have recently been identified as important regulators of gene expression, in particular, in bacteria. A theoretical study shows that RNAs that have very different secondary structures with near-groundstate energy, that is, potential riboswitches, are relatively frequent and easily accessible in evolution. The secondary structure model furthermore allows estimates of energy barriers and even entire folding trajectories. An impressive experimental study demonstrates that a single sequence can have two distinct functional ribozyme structures. Heuristic algorithms can be used to design sequences with two near groundstates. The case of more than two alternative structures is only partially understood.

Small subunit ribosomal RNAs are probably the most frequently used data sets in molecular phylogenetics. Most studies assume that individual sequence positions evolve at least approximately independently of each other. This is, however, at odds with the fact that rRNAs form stable secondary structures that are very well preserved over very long timescales. Selection for stabilizing RNA structure is seen in many types of structural RNA sequences. Nucleotides in stem regions evolve in strong correlation with their pairing counterpart. More elaborate scoring schemes and even associated maximum likelihood techniques acting directly on RNA secondary structures are algorithmically relatively unproblematic but will require detailed knowledge about the dynamics of RNA structure evolution. While the structures of many RNA families change very little, for example within vertebrates, significant changes of the structure, however, are evident at timescales of the divergence of the major metazoan phyla. As a consequence, not only fixed secondary structures but the evolution of the structures themselves need to be taken into account. Secondary structures have rarely been used in molecular phylogenetics so far. An exception is the investigation into the history of RNase P and RNase MRP RNAs by Davin Penny and coworkers, which demonstrates that ''RNA secondary structure is useful for evaluating evolutionary relatedness, even with sequences that cannot be aligned with confidence''. More recently, cladistic analyses based on RNA secondary structure have demonstrated this point convincingly, in particular at the level of deep phylogenies.

Keywords

Base Pairing
Two nitrogen bases stabilized by the formation of hydrogen bonds. Two complementary RNA regions are connected by base pairing and form a double helix.

Base Stacking
Two nitrogen bases stabilized by induced dipole.

Graph
Data structure consisting of nodes and edges between pairs of nodes.

Leadzyme
A catalytic RNA that cleaves a specific ribophosphodiester bond in the presence of lead ions.

MC-Sym
Macromolecular conformations by symbolic programming.

Motif
A recurring structural element of biological significance.

Spanning Tree
A tree that includes every node of a graph.

tRNA:	Transfer RNA
RMSD:	Root mean square deviation

The knowledge of the 3-D structure of an RNA molecule gives us indications about which other molecules it can interact with, and how its biochemical function is achieved or can be modified. Unfortunately, direct structure determination methods, such as X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, and electron microscopy, cannot be applied at the rate of the genomics era yet, limiting the deciphering of RNA folding and structure. The recent resolution of the large ribosomal subunit (LSU) crystal structure represented a leaping step, but it has mainly pointed out the weaknesses of the current methods for analyzing and inspecting RNA 3-D structures. At this time, RNA sequences of predetermined function cannot be designed and folded properly. Further analysis and interpretations of the available 3-D structures are thus needed to bring additional insights into RNA function. Here, we present state-of-the-art data structures and algorithms that were developed in the last 10 years to analyze and inspect efficiently and objectively RNA 3-D structures. As you will realize by reading the following sections, they are the same as those employed in the development of the best computer modeling methods of RNA 3-D structures.

1 Goal

During the past 10 years, computational studies of RNA 3-D structures were focused on the gathering of experimental data and knowledge, as well as on the development of computer formalisms to represent structural data precisely and accurately. Formalized structural data and knowledge can be exploited by using computer modeling tools to generate precise and unbiased RNA 3-D structures. Computer generated 3-D structures give new insights about the function of a given RNA, which can be challenged experimentally. Again, the data obtained from experimental verification are sent for computer analysis; from which keener structural hypotheses will be made.

The flowchart in Fig. 1 indicates the principal components of computer modeling. The respective human modeler and computer contributions are shown separately. The arrows highlight the principal activities of computer modeling. The role of computer programs, delimited by a shaded box in Fig. 1, is to generate systematic and objective 3-D models. The modeler's contribution consists in developing computer formalisms and programs. In the context of a given data formalism, computer programs model 3-D structures: search structural motifs (Sect. 2), and build (Sect. 3) and refine (Sect. 4) 3-D structures. The resulting RNA 3-D models are interpreted by the modeler and help improve the computer formalisms and programs for the next development cycle. Symbolic annotation is another computer program that can assist the modeler in interpreting the 3-D models, by automatically identifying and formalizing structural data from 3-D models.

The long-term goal of computer modeling is to drive precise and efficient wet laboratory experiments by generating the most plausible 3-D models, and by supporting structural hypotheses that can be tested experimentally. Thus, the use of computer modeling of RNA 3-D structures is a tool in the hands of the experimentalists to catalyze the production of precise 3-D models (Sect. 5).

2 Structural Knowledge

In this section, we introduce three levels of abstraction that are relevant to the representation of RNA 3-D structural knowledge and, thus, to the building of RNA 3-D computer modeling systems. The mathematical and computer formalisms were deduced from the observation of high-resolution RNA structures (X-ray crystal structures of 3 Å resolution or better), and serve as first-class objects in the description of 3-D structure building algorithms. It is mandatory for computer systems to describe formally the structural information to drive the building engine accurately. In Sect. 2.1, we present the RNA polymer and nucleotide conformations. In Sect. 2.2, we introduce the nucleotide noncovalent interactions, base pairing, and base stacking. Finally, in Sect. 2.3, a computational formalism to encode arrangements of nucleotide interactions is developed.

2.1 Nucleotide Conformations

RNAs are polymers of linked ribonucleotides (or nucleotides for short). As shown in Fig. 2(a), each nucleotide in the chain contains a ribose sugar, a phosphate group (P attached to four O atoms), and a nitrogen base (or simply base) that is one of adenine (A), guanine (G), cytosine (C), or uracil (U) (Fig. 2b). The ribose sugar is linked to the phosphate group through the C5′−O5′ diester bond. The O5′ is covalently linked to the P, which in turn is linked to the O3′ of the next nucleotide. The O3′ forms a second diester bond with the C3′, which is why the connection between two nucleotides in RNAs is referred to as a *phosphodiester linkage*. The ribose sugar is linked to the base through the C1′−N glycosidic bond (the N in the base is N9 in the purines A and G, and N1 in the pyrimidine C and U).

In general, computer modeling system developers define data structures that maintain at all time the atomic coordinates of all atoms, from which it is easy to compute the covalent bond lengths and angles, as well as the torsion angles (see Fig. 2c). As a fair approximation, the covalent bond lengths and angles are initialized at optimal and predetermined values that are kept fixed during modeling. The torsion angles, on the other hand, parameterize nucleotide conformations and are free to change. Six torsions are located along the phosphodiester linkage (α, β, γ, δ, ε, and ζ); five within the ribose sugar (θ_0 to θ_4), and one around the glycosidic bond (χ) (see Fig. 2a). The glycosidic torsion is measured using the atoms O4′−C1′−N9−C4 in purines, and using the atoms O4′−C1′−N1−C2 in pyrimidines. All torsions along the backbone, as well as the glycosidic torsion, are free to rotate almost independently. However, the ribose ring stereochemistry imposes a relation among the θ_0 to θ_4 torsions that can be expressed by a cosine function,

$$\theta_j = \theta_{\max} \cos(\rho + j\varphi) \qquad (1)$$

where $j = 0$ to 4 and $\varphi = 144^\circ$ ($720^\circ/5$). When $j = 0$, we have:

$$\theta_0 = \theta_{\max} \cos(\rho) \qquad (2)$$

In equation (1) and (2), ρ is the pseudorotation of the ribose ring. By varying ρ from 0 to 360° by steps of 90°, θ_0 goes from $\theta_{\max}$ to 0, to $-\theta_{\max}$, back to 0, and finally back to $\theta_{\max}$. The $\theta_{\max}$ value is reached twice, at the initial conformation ($\rho = 0$, as $\cos(0) = 1$) and at $\rho = 360^\circ$. At each

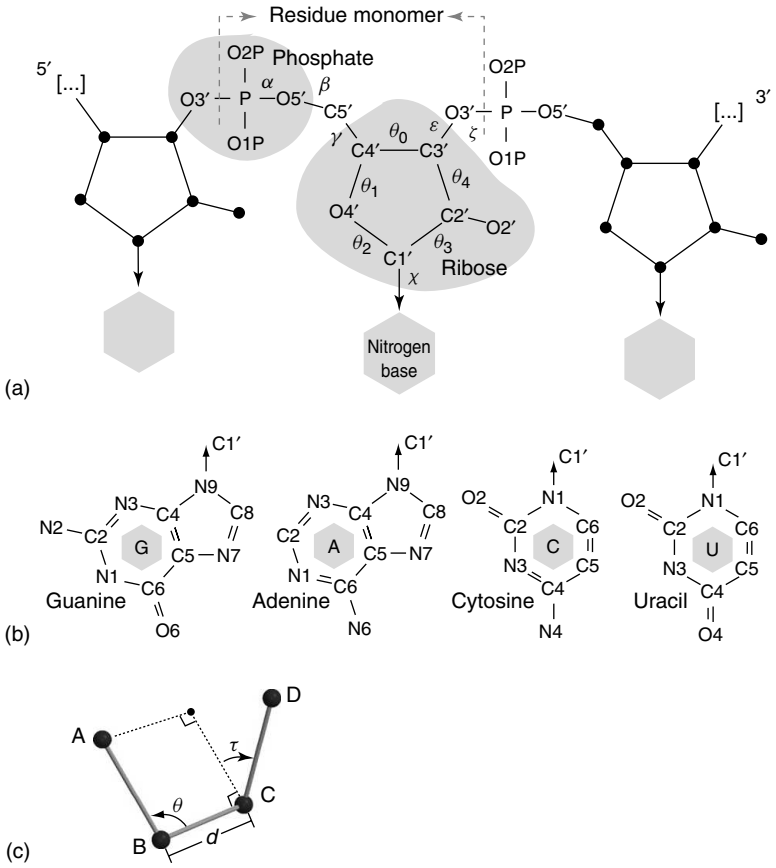

Fig. 2 Nucleotide. (a) Atomic numbering and torsion angles nomenclature presented on a suite of residue monomers, delimited by dashed arrows. The residue's subgroups are highlighted in light gray: phosphate group, ribose, and one of the four possible nitrogenous bases. (b) The four nitrogenous bases and their atomic numbering. (c) Definition of bond length (d), angle (θ) and torsion (τ) on four consecutively covalently bonded atoms A, B, C, and D.

step of $\rho + 180^\circ$, the sign of all torsions is inversed, corresponding to the mirror image of the conformation at ρ. A useful equation is derived from Equation (1), which determines ρ:

$$\tan\rho = \frac{(\theta_2 + \theta_4) - (\theta_1 + \theta_3)}{2\theta_0(\sin 36^\circ + \sin 72^\circ)} \qquad (3)$$

Equation (2) determines θ_{max}.

The pseudorotation quantifies the puckering mode of the ribose, traditionally labeled by its ''envelope'' and ''twist'' (half-chair) geometries. The ''envelope'' geometry is observed when one atom is located over or below the plane formed by the four others, whereas the ''twist'' geometry is observed when one atom is over and another is below the plane formed by the three others. When the plane is horizontal and the C5′ atom is on the left side, the atoms located over the plane are said to be endo to the C5′, and those located below

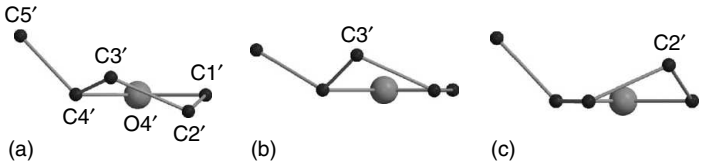

Fig. 3 Reference and main ribose pucker modes. (a) The $^2T_3$ twist shape C2′-*exo*–C3′-*endo*. (b) The ^3E envelope shape C3′-*endo*. (c) The ^2E envelope shape C2′-*endo*.

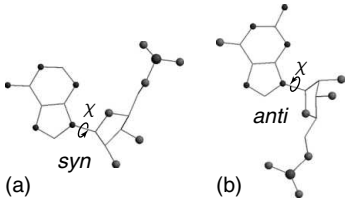

Fig. 4 The main RNA glycosidic bond torsions. The sphere's radius is proportional to the represented atom's proton mass: nitrogen, oxygen, and phosphate in ascending order. Carbons were omitted. The bond torsion is χ. (a) The syn torsion aligns the base and the backbone in the same direction. (b) The anti torsion aligns the base and the backbone in opposite direction.

the plane are said to be exo to the C5′. A convenient nomenclature is to use the letters "E" for *envelope* and "T" for *twist* conformations, and the atom number as an exponent for the endo, and as an index for the exo atoms. As described earlier, the convention is to choose $\rho = 0^\circ$ when θ_0 is positive and maximum, which results in the C2′-*exo*–C3′-*endo* conformation, or $^3T_2$ using the nomenclature shown in Fig. 3a'. Note the mirror image of the initial conformation is $^2T_3$, reached at $\rho = 180^\circ$.

RNAs are characterized by two principal "envelope" puckering modes, the C3′-*endo* (^3E) typical of the A-form helix (see Fig. 3b) and the C2′-*endo* (^2E) typical of the B-form helix (Fig. 3c). The B-form helix is prevented from forming because of steric conflicts created by the 2′-OH group of the ribose, although isolated B-form conformations may be found at the extremities of A-form helices, such as U_7 in the yeast tRNA-Phe, and within loops. RNAs are also dominated by two favored glycosidic bond torsions. In the syn conformation (Fig. 4a), $0^\circ < \chi < 90^\circ$, the bulk of the base is oriented toward the sugar group. In the anti conformation (Fig. 4b), $-120^\circ < \chi < 180^\circ$, the bulk of the base is in the direction opposite to the sugar group. The nucleotide conformations in both the A-form and B-form helices adopt the anti conformation.

Many attempts were made to classify the nucleotides conformations according to the six phosphodiester linkage torsion angles. In the 1970s, Olson presented a statistical analysis where the six phosphodiester torsions were reduced to two virtual angles spanning the two C4′−C−O−P segments. They reported a correlation among the single torsions showing that they are not completely independent. Gautheret, Major, and Cedergren have superimposed the $P_n-O3'_{n+1}$ atoms of dinucleotides (adjacent nucleotides) and used root mean square deviation (RMSD) to reduce the classification problem to one dimension. They were able to form a small number of dinucleotide clusters according to

the orientation of the P−P vector (backbone direction), and used them in early versions of their *MC-Sym* RNA modeling computer system to sample the conformational space of RNAs. They noticed a great variability of the torsion values in each cluster, also known as the *crankshaft* effect. More recently to analyze the ribosomal RNA (rRNA) structures, Duarte and Pyle have taken an approach similar to Olson's and simplified the six backbone torsions to two pseudorotations, $\eta(C4'_{n-1}-P_n-C4'_n-P_{n+1})$ and $\theta(P_n-C4'_n-P_{n+1}-C4'_{n+1})$. They reported torsion motifs found in consecutive nucleotides. Others have classified the torsions by using unsupervised machine learning approaches. Hershkovitz and coworkers have proposed discrete torsion values on the basis of Gaussian distribution data fitting of the four backbone torsions α, γ, δ, and ζ. They identified 37 nucleotide ''signatures'' (or conformers) in the large ribosomal subunit (LSU) crystal structure of *Haloarcula marismortui*.

Others have proposed the analysis of three torsions at a time in order to visualize the results of clustering in 3-D. Murray and her colleagues have identified 42 nucleotide conformers by applying quality filtering techniques to high-resolution crystal structures. They grouped the torsions in two triplets: (α, β, γ) and (δ, ε, ζ). The 3-D distributions of each triplet were plotted, and their peaks were visualized and aligned to define the nucleotide conformers. Each nucleotide conformer represents a high quality reference nucleotide conformation. Schneider and coworkers have analyzed the torsion angles of dinucleotides by Fourier averaging of six selected 3-D distributions. They found 18 dinucleotide conformers not belonging to the overrepresented A-type conformation family. Similar to Gautheret, Major and Cedergren, they concluded the structural conformational space of RNA 3-D structures, which could be sampled by a small number of dinucleotide conformers.

2.2 Nucleotide Interactions

In addition to the covalent linkage, two nucleotides can be related in 3-D space by base stacking and base pairing.

2.2.1 Base Stacking

Base stacking involves London dispersion between two bases that favor an arrangement where one base is stacked on top of the other. Base stacking can be evaluated by defining and comparing base planes. In pyrimidines, a base plane normal vector can be defined using a right-handed rotation around the base ring atoms N1, C2, N3, C4, C5, and C6 (see Fig. 5a). If the same atoms in the same sequence are used in purines, then the base plane normal vector is defined by a left-handed rotation. Considering the normal to the base plane vector orientations, then base stacking can adopt four different arrangements (Fig. 5b).

2.2.2 Base Pairing

Base pairing involves the formation of hydrogen bonds (HB) between hydrogen donor groups (mainly NH and NH_2) and acceptor groups (mainly CO and N) located along the base edges. The formation of two or more HBs induces a quasi-coplanar arrangement of the two interacting bases. Canonical G=C and A−U Watson–Crick bps (see Fig. 6) are the most frequent and dominate RNA folding. Stretches of stacked Watson–Crick bps adopt the A-RNA double-helix conformation, and are

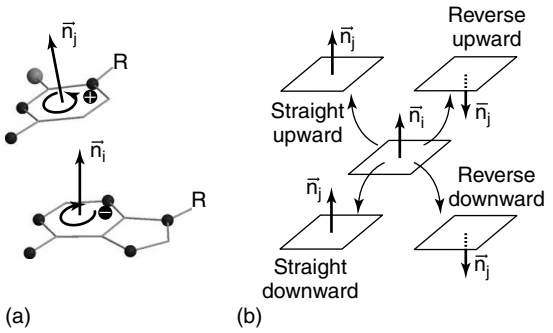

Fig. 5 Base stacking. (a) Straight upward base stacking between a purine (below) and a pyrimidine (above). A base plane in purines is defined in a left-handed coordinate system (−), whereas it is defined in a right-handed coordinate system (+) in pyrimidines. (b) The four possible relative orientations of base stacking according to the direction of the normal vectors to the base plane, n_i (origin base) and n_j (destination base). The bases are represented by squares and the origin to destination direction is indicated by the arrows.

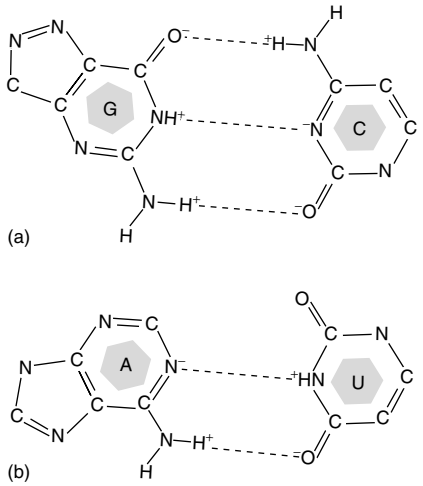

Fig. 6 Canonical Watson–Crick base pairs. The dotted lines indicate HBs. (a) G=C. (b) A−U.

called *stems* or simply *helices*; they form the RNA secondary structure. Dynamic programming is used to determine the optimal secondary structure of an RNA sequence, although the optimal and actual structures can differ considerably. In general, for simplification, helices are considered as rigid objects in computer modeling.

Non–Watson–Crick bps, often qualified as noncanonical, are also present in RNA 3-D structures. All sixteen combinations with various HB patterns have been observed. Their number varies, from 20% of the yeast tRNA-Phe crystal structure bps to as high as 50% of the LSU bps. The nucleotides not involved in the secondary structure have a tendency to stack in roughly helical conformation and to form noncanonical bps.

2.2.3 Base Pairing Nomenclatures

The classical and highly referred bp catalog of Saenger contains 28 base pairing patterns, which were labeled by roman numbers. However, roman numbers are not convenient to human discussions, and common names were thus given to the most frequent ones (cf. ''wobble G−U'',

''Hoogsteen A−U'', ''reverse Hoogsteen A−U'', ''sheared G−A'', etc).

Leontis and Westhof proposed a more formal and systematic base pairing nomenclature (*LW*) to simplify discussions and to suggest bp geometries directly from the names. They defined for each base three contact edges: the Watson–Crick (*W*), Hoogsteen (*H*), and Sugar (*S*) (see Fig. 7a). The nomenclature is rapidly inferred from a quick observation of the 3-D structure of a bp, as the edges involved in

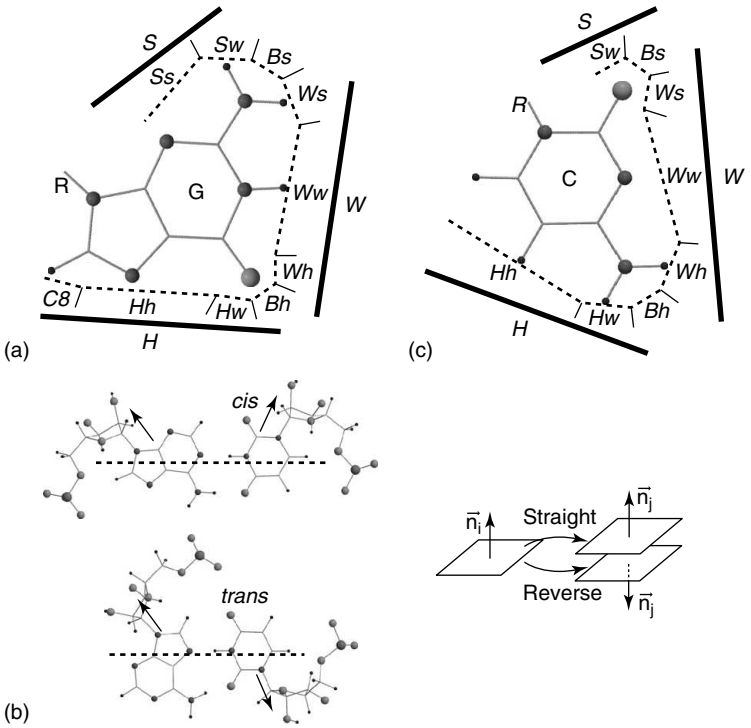

Fig. 7 *LW*+ base pair nomenclature. (a) The interacting faces and edges of guanine (G) and cytosine (C) (the same faces and edges were also assigned to adenosine and uracil). ''*S*'' sugar; ''*W*'' Watson–Crick; ''*H*'' Hoogsteen. The sphere's radius is proportional to the represented atom's proton mass: hydrogen, nitrogen, and oxygen in ascending size order. Carbons are omitted. The backbone connects at ''R.'' The three *LW* edges are highlighted in dark bands, forming roughly a triangular shape around the base. The dotted lines delimit the *LW*+ faces. ''*B*'' stands for a bifurcated hydrogen bond, and ''*C8*'' is used to label an additional possible interaction that occurs only in purines. (b) The backbone relative orientation. The dotted line represents a plane perpendicular to an imaginary bp plane. As indicated by the arrows, cis: the backbone of both bases enters the same side of the perpendicular plane; trans: the backbones point in opposite sides of the perpendicular plane. (c) The base pair relative orientation. The curved arrows indicate HBs. The straight arrows indicate the normal vectors to the base planes, n_i and n_j (defined in Fig 5). Straight: the normal vectors point to the same direction; Reverse: the normal vectors are in opposite directions.

HB formation can easily be identified. The vectors formed by N1 (in pyrimidines) or N9 (in purines) to C1′ in each base complement the nomenclature by the assignment of the cis or trans relative orientation of the bp (see Fig. 7b). Using the *LW* nomenclature, a standard Watson–Crick bp is referred to as a "*W/W cis*" bp.

To increase the precision in computer modeling, Lemieux and Major slightly extended the *LW* base pairing nomenclature by subdividing each edge in faces (*LW+*), and resolved small ambiguities introduced by the formation of single HB bps (see Fig. 7a). For instance, in *LW*, a GU wobble bp is named "*W/W cis*" (the same as Watson–Crick), whereas in *LW+* it is more precisely named *Ww/Ws cis*. If the relative orientation between each base plane normal vectors is added ("straight" is used for the same orientations, and "reverse" is used otherwise; see Fig. 7c), the bp geometry described by the nomenclature is completely unambiguous.

Lee and Gutell proposed an alternative base pairing nomenclature (*LG*), after visually examining the bps present in the LSU crystal structures of *Thermus thermophilus* and *H. marismortui*. They presented a topological relationship that starts at the canonical C=G or A−U *cis* Watson–Crick bps, or at the *cis* wobble G−U bp, and that extends to 14 families by successive manipulations of the base planes and glycosidic bond relative orientations: shearing, flipping, reversing, paralleling, or slipping. The 14 families are the Watson–Crick (*WC*), wobble (*Wb*), slipped Watson–Crick (*sWC*), slipped wobble (*sWb*), reversed Watson–Crick (*rWC*), reversed wobble (*rWb*), Hoogsteen (*H*), reversed Hoogsteen (*rH*), sheared (*S*), reversed sheared (*rS*), flipped sheared (*fS*), parallel flipped sheared (*pfS*), parallel sheared (*pS*), and reversed parallel sheared (*rpS*).

2.2.4 Structure Annotation

Structure annotation is an activity consisting of symbolic labeling of the nucleotide conformations and interactions from an input RNA 3-D structure. Annotated 3-D structures are simpler to analyze than 3-D coordinates. The annotation of nucleotide conformation is done by inferring the sugar pucker modes and the glycosidic torsion directly from the nucleotide torsion angles. The annotation of base stacking is done by computing and comparing the normal base plane vectors. Finally, the annotation of bps requires the computation of the HBs followed by the appropriate name assignment from a chosen nomenclature.

Structure annotation can be done by interactive computer graphics, by looking at a structure and describing the conformations and interactions. Structure annotation can also be automated by computer programs. Using the JUMNA system (see Sect. 4), Harvey and coworkers have implemented molecular mechanics restraints to identify bases that stack and pair, but they did not implement any labeling. Gendron, Lemieux, and Major have developed a computer program, *MC-Annotate*, which identifies geometrically and labels the bases involved in stacking and pairing. Bases that stack are identified by applying the Gabb and coworkers geometrical method. The bps are identified by applying an unsupervised machine learning approach in which three HB geometric parameters were defined and modeled using a series of Gaussian distributions. Potential HBs are identified and are assigned probabilities. For each identified bp, the probabilities are used to determine the most likely HB pattern that applies. It is then easy to assign the appropriate bp name according to any of the proposed nomenclatures; although the current implementation uses the *LW+*

nomenclature. The *MC-Annotate* program has been made available on the Web, and can be queried online (currently at www.lbit.iro.umontreal.ca/mcannotate).

Westhof and coworkers have proposed a simpler annotation system that was implemented in the *RNAView* program. Their annotation is fully based on geometrical features, and predetermined cutoff values are used to accept or reject a bp. The labeling is made according to the general *LW* nomenclature. *RNAView* is accessible on the Web (currently stored at www.ndbserver.rutgers.edu/services).

2.2.5 Isosteric Base Pairs

Two bps that preserve a local 3-D structure are said to be isosteric, and can appear in evolutionary related structures to preserve function. Leontis and coworkers have superimposed the geometry of all possible bps according to their C1′−C1′ distances and cis/trans base orientations. They then mapped all 16 combinations to the 12 families of their *LW* nomenclature, which resulted in isostericity matrices that can be consulted on the Web (currently stored at www.bgsu.edu/departments/chem/RNA/pages). It was shown clearly from these studies that all standard Watson–Crick combinations are isosteric, and the wobble G−U bp is isosteric to the protonated A−C bp.

Walberer and coworkers proposed to quantify the isostericity between two bps by a value reflecting the overlapping of the four glycosidic bonds, a measure more representative than the C1′−C1′ distances. They observed high isostericity values not only in the helical bps but also in several all purine and all pyrimide base pairing overlaps. So far, base pairing studies have supported the hypothesis that evolution maintains RNA structure more tightly than sequence. Consequently, covariations reflecting bp isostericity must be evaluated when comparing RNA sequences. Accurate sequence comparison requires precise sequence alignment to ensure that the positions compared are indeed homologous. Despite the practical problems, sequence comparison, from which covariations can be identified, greatly benefits secondary structure determination.

2.3 Motifs

The function of RNA is established by the presence of specific and recurrent arrangements of base interactions, other than the canonical stems. Researchers in the field refer to these arrangements as *motifs*. Prior to the resolution of the LSU, many of these motifs were predicted from comparative sequence analysis. Short oligomers containing the predicted motifs have been experimentally studied, and X-ray crystallography and nuclear magnetic resonance (NMR) assays have revealed their 3-D structures. Later, the motif structures were confirmed to form in the crystal structure of the LSU as well.

2.3.1 Motifs and Function

As RNA motifs point to function, the search for new motifs in the LSU, and in other previously determined 3-D structures, has thus become the focus of several theoretical studies. RNA motifs are thermodynamically stable and fold similarly in many different environments, whether in short or large structures, suggesting they might be considered to be the fundamental RNA building blocks. Consequently, the determination and prediction of RNA motifs could help study the RNA folding mechanisms, as well as predict the native structure of RNA directly from its sequence of nucleotides.

There are a limited number of published RNA motif studies, and they are generally made by teams of researchers that have introduced computer formalisms for nucleotide interactions (see Sect. 2.2).

Inside a computer, a data structure that is convenient to represent RNA motifs is the graph. An RNA graph has nucleotide nodes that are connected by interaction edges. Consequently, the RNA motif searching problem can be reduced to matching RNA subgraphs (putative motifs) to full RNA graphs (structures). Major and his coworkers have implemented a motif searching engine, *MC-Search,* which uses the annotations described earlier from the augmented Leontis and Westhof nomenclature, *LW+*, and the computer program *MC-Annotate*. The input of *MC-Search* is the target RNA subgraph (motif) and the RNA structures to be scanned.

2.3.2 Sarcin/Ricin Motif

For example, searching for the generic sarcin/ricin motif (see Fig. 8) in the *H. marismortui* 23S and 5S rRNA structures generates five hits, which share a minimal RMSD of 0.73 Å (An RMSD of 1 Å or less is considered very close for structures of this size.).Note that no coordinates are given in the input, as the subgraph for the motif contains only the symbols

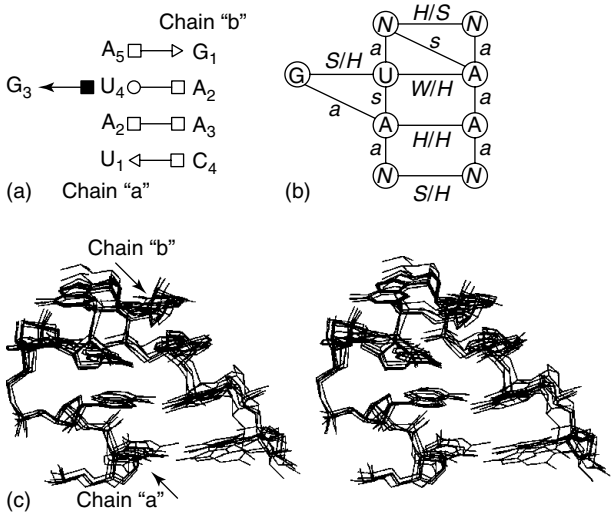

Fig. 8 Sarcin/ricin motif. (a) Base interactions. The *LW* annotation is used. The circles indicate the *W* edge, the squares the *H* edge, and the triangles the *S* edge. The white circles, squares, and triangles indicate the trans backbone orientation, whereas the black symbols indicate the cis backbone orientation. (b) RNA graph used for the input of *MC-Search* to find the sarcin/ricin motifs in *H. marismortui* 23S and 5S rRNA. ''*a*'' indicates sequence adjacency and ''*s*'' indicates base stacking. The letters that label the edges correspond to the *LW* base edges. ''*N*'' stands for any base. (c) Stereo view of five superimposed motifs matched by *MC-Search*. The hydrogen atoms were omitted.

representing each nucleotide interaction. These motifs were also found by Leontis and his coworkers by visual examination. Interestingly, bp S/H $U_{a1}C_{b4}$ can be substituted by an S/H C−C or G−A bps, as seen in other instances of the motif; represented by the generic S/H N−N interaction in the RNA graph of the motif (see Fig. 8b). These three bps belong to the same isosteric family, as discussed in Sect. 2.2.5, and as confirmed by the very small RMSD. Furthermore, if we remove the nonadjacent stacking interactions, $A_{a2}U_{a4}$ and $A_{a5}A_{b2}$, from the target motif, a sixth motif occurrence is found. The new motif instance, which does not include the nonadjacent stacking interactions, shares a RMSD of 5.2 Å with the five others, strongly suggesting the nonadjacent stacking interactions are a requirement of the sarcin/ricin motif.

The SCOR (structural classification of RNA) database contains several examples of published and visually identified RNA motifs and their references to the appropriate 3-D structures.

3 Structure Building

There are two major approaches to RNA 3-D structure modeling: folding and assemblage. Folding methods start with an initial model, usually extended or randomized. The initial model is then successively modified until a final and satisfactory model is identified. The conformational space of folding methods is defined by the number of models that can be reached from the modifications.

Molecular mechanics is a folding method that uses an objective function to evaluate the succeeding models and guide the modifications toward optimal states. Harvey and his coworkers have developed an objective function for RNA that is mainly composed of experimentally determined nucleotide interaction constraint terms in order to emphasize their formation in the final models. They defined in their computer modeling system, *YAMMP*, one to five points per nucleotide to simplify the folding operations, as they wanted to apply it to large RNAs. Other terms in the objective function were present to ensure the appropriate stereochemistry of the models. *YAMMP* has been used by Harvey and coworkers to model the subunits of the ribosomal RNA in the early 1990s.

Assemblage methods start from scratch. The components of the RNA are assembled using construction operators that place them in 3-D space, relatively to the other already positioned components. In this section, we describe automated and interactive assemblage methods, as they are the two variants that were mainly employed in the last 10 years to propose RNA 3-D structures. We will describe *MC-Sym*, a constraint satisfaction problem solver, and *MANIP* an interactive computer graphics system.

In Sect. 3.1, the constraint satisfaction problem is introduced. In Sect. 3.2, the search space of RNA 3-D structures is defined. In Sect. 3.3, the backtracking algorithm to solve the RNA CSP (constraint satisfaction problem) is presented, and, in Sect. 3.4, the interactive computer graphics approach is described.

3.1 Constraint Satisfaction Problem

The RNA 3-D structure building problem can be described in terms of a more general problem, well known by computer scientists: the constraint satisfaction

problem or CSP. The CSP is defined by a set of variables that need to be assigned discrete values from finite domains to satisfy a set of predetermined constraints. The number of variables and the size of the domains define the CSP search space. Solving the CSP consists in finding one, many, or all possible assignments that respect the constraints. The constraints are applicable to one or more variables and restrict the number of possible assignments.

A classical CSP is the 8-queen problem: 8 queens must be positioned on a standard 8×8 checker board in such a way that each queen is safe from the others. In the 8-queen problem, we have 8 variables (the queens), the 64 possible positions for each queen, and three constraints; two queens cannot be positioned in the same row, column, or diagonal. There are 92 solutions to this problem; 92 ways of positioning 8 queens on a regular 8×8 checker board so that no queen can attack another.

3.2 Search Space

3.2.1 Nucleotide Frames

To help visualize RNA search space, consider an RNA structure as a set of nucleotides that are all related to each other by spatial transformations composed of rotations and translations. Major and coworkers have parameterized nucleotide transformations by defining a local base referential, or frame, whose origin is placed on the terminal nitrogen atom (N9 for purines and N1 for pyrimidines), and *XY* plane aligned to the base plane (see Fig. 9a).

The frame of a base, A, is represented by the 4×4 homogeneous transformation matrix, ${}^{O}T_{A}$, that encodes the transformation (rotation and translation), which applied to the global origin, O, results in the frame of base A. Symmetrically, applying the inverse matrix of A's local base frame, ${}^{O}T_{A}{}^{-1}$, results in O. From the local base frames, one can compute the transformation matrices that relate any base interactions in an RNA 3-D structure. Consider the bp in Fig. 9a, the relative transformation from frame A to frame B is expressed by the product ${}^{A}T_{B} = {}^{O}T_{A}{}^{-1} \times {}^{O}T_{B}$.

Now, to reproduce an observed relation, ${}^{M}T_{N}$, when M is already positioned, we apply the transformation ${}^{O}T_{N} = {}^{O}T_{M} \times {}^{M}T_{N}$ to the coordinates of base N. First, we need to place N in M's frame, by using the transformation ${}^{M}T_{N}$, and, second, since N is now local to M, we move N by the global frame of M, ${}^{O}T_{M}$ (see Fig. 9b). The coordinates of base N in the previous example are assumed to be expressed in the global O, a task

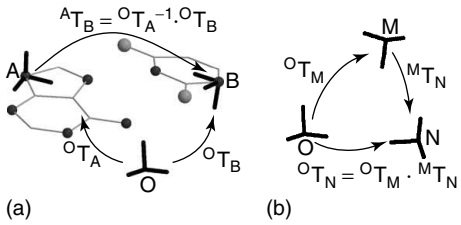

Fig. 9 Base frame transformation. (a) Base coordinate frame transformation. The base A and B local referentials (frames) and the origin global referential are shown using small bold axis systems. The frame transformation, ${}^{A}T_{B}$, allows us to express the B to A relation independently of the position of base A and of the global referential, O, and can be computed directly from base A and B frames, ${}^{O}T_{A}$ and ${}^{O}T_{B}$. (b) Application of base frame transformations. Base N is first put in the local referential of base M, by using the base frame transformation ${}^{M}T_{N}$, and then to the global referential by using the base frame transformation ${}^{O}T_{M}$.

that can be precomputed to accelerate building.

3.2.2 Variable Assignments

The building procedure consists in positioning n bases using $n-1$ transformations, and can be represented by an ordered spanning tree of the RNA graph (see Fig. 10). The $n-1$ transformations are mapped to the edges of the spanning tree, which define the CSP variables. In Major's laboratory, a computer program has been designed to extract the frames of all nucleotides in available RNA structures, and then using the frame manipulation given above, to produce a database of RNA base relative transformations. The list of 4×4 matrices (mainly obtained from the structures of high resolution in the PDB and NDB) is mapped to each type of nucleotide interactions described in Sect. 2.2.

The RNA CSP search space is thus defined by the Cartesian product of the transformation matrices from the database that can be assigned to each edge in the spanning tree of the RNA graph. In practice, the relevant characteristics of each interaction are specified by the user. The computer modeling program synchronizes with the database to extract a set of transformations that optimizes the search space according to the user's characteristics. The other task of the user is to define the ordered spanning tree, as only one tree is solved by run. If several trees need to be considered, then they must be defined and searched independently.

3.2.3 Building a GNRA Tetraloop

Consider modeling the 3-D structure of the 5′-CGGGAG-3′ sequence. The task of the user, as mentioned earlier, is to introduce an ordered spanning tree of the RNA graph

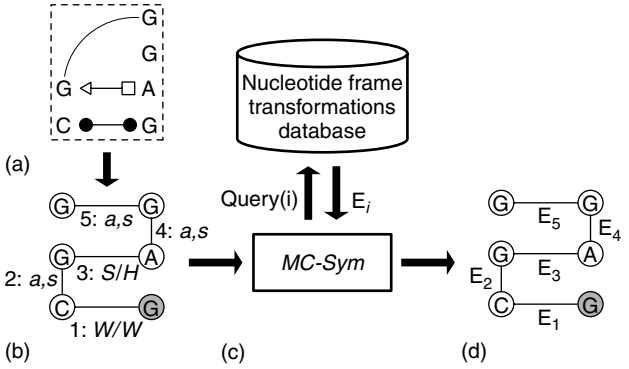

Fig. 10 *MC-Sym* search space for the GNRA motif. (a) Base interactions. The annotations follow *LW* (as in Fig. 8). (b) A user chosen ordered spanning tree and edge characteristics for (a). ''*a*'' stands for sequence adjacency, and ''*s*'' for stacking. The shaded base is the spanning tree root, or modeling reference. (c) *MC-Sym* database communication. The transformation set for each edge in the spanning tree is extracted from the nucleotide frame transformations database. The ith edge translates in query(i), which returns transformation set E_i. (d) Search space. The Cartesian product of the transformation sets defines the search space, and *MC-Sym* is ready for backtracking.

of Fig. 10(a), by employing the symbols described in Sect. 2.2. Figure 10(b) shows one possible ordered spanning tree of this RNA graph. The input spanning tree instructs *MC-Sym* to obtain from the database the transformations that match the input characteristics of each interaction edge in the tree (Fig. 10c), defining this modeling problem's search space.

Here the user selected the G in the Watson–Crick bp as the root of the spanning tree. Figure 10(d) shows the user chosen order in which *MC-Sym* will build the structures. The C of the Watson–Crick bp is placed from the G using *W*/*W* cis transformations. The edges are labeled E_1 to E_5. E_1: given C is placed, the G of the G–A bp is positioned by applying adjacent/stack transformations from the C in the Watson–Crick bp. E_2: the G of the G–A bp is positioned by applying adjacent/stack transformations from the C in the Watson–Crick bp. E_3: the A of the G–A bp is positioned by applying S/H cis transformations. E_4: the G that stacks on top of the A in the G–A bp is placed by applying adjacent/stack transformations. Finally, E_5: adjacent/stack transformations are also applied to get the final G in the tree.

3.3 Backtracking

In the *MC-Sym*'s search space defined earlier, one transformation assigned to each edge in the spanning tree places the bases of the structure in 3-D space. The chosen transformations are applied systematically to the edges of the ordered spanning tree. However, what happens if an assignment creates atomic clashes in the structure? *MC-Sym* includes atomic clashes as constraints to be satisfied, typically by defining a distance threshold of 1 Å on all atoms. Consequently, the constructions containing atoms positioned closer than 1 Å apart are eliminated.

When a constraint is not satisfied or all transformations for a given edge have been tried, *MC-Sym* returns (backtracks) to the last assigned edge (variable). The next transformation is selected and the search continues until all transformations have been tried for each edge.

3.3.1 Experimental Constraints

User constraints that address the nucleotide conformations, such as sugar pucker modes, glycosidic torsions, atomic distances, bond angles and torsions, or base interactions can also be added to the constraints to ensure the generated structures include the structural features that were observed experimentally or predicted theoretically.

Theoretical bps can be derived from secondary structure, covariation and tertiary interaction predictions. Experimental bps can be derived from site-directed mutagenesis, a palliative to the lack of sequence variation. Monitoring of the RNA activity while specific and strategic bases are replaced can detect base interactions. The use of modified nucleotides can detect the participation of specific chemical groups, such as hydroxyls, phosphates, oxygens, amino, and imino, in the activity and interactions. The use of chemical modifications can provide enough data for the construction of accurate local sites, and in particular catalytic sites. Chemical and enzymatic probes cleave at specific sites or attack specific groups that are exposed to the solvent. The results of such probing are highly qualitative rather than quantitative, but, nevertheless, have been used to confirm secondary and tertiary structure elements of several RNAs. Cross-linking regions of an RNA by creating artificial covalent bonds, using for

instance UV irradiation, allows one to establish the proximities of some atoms and nucleotides that can then be used as powerful constraints in RNA modeling. NMR is a powerful technique that provides precise interatomic distances that can then be translated easily in nucleotide conformation and interaction characteristics.

3.3.2 Search Tree and Time Complexity

The time complexity of the backtracking algorithm is exponential in both the number of edges (N) and the number of transformations for each edge (M). The backtracking procedure develops a search tree, where each node is a partial assignment. The depth of the search tree is determined by N, and its width is determined by M. When a partial assignment is invalidated, the portion of the search tree under the current assignment node is pruned, as no valid solution can exist in that portion of the search tree. Assuming the complexity for checking partial assignments is constant, the time for completing a search is reduced proportionally to the efficiency of pruning the search tree. Consequently, in practice *MC-Sym* applies to small or highly constrained RNAs.

3.3.3 Backbone Construction

How is the backbone handled? So far, we have paid attention to the bases and their interactions. Here we turn the focus to the backbone. In the original versions of *MC-Sym*, the whole nucleotide (base, phosphate group, and ribose) was moved with the base transformations. In this context, the nucleotide was considered a rigid body sampled by various atomic coordinates, corresponding to the sugar puckers modes and glycosidic torsions specified by the user (see Sect. 2.1). The nucleotide conformation sampling increased the search space. The use of rigid nucleotides created an additional constraint to be verified, the length of the O3′-P bond, which connects two consecutive nucleotides in the sequence.

However, the results of recent studies on RNA backbones by Thibault and Major have shown that a more efficient approach can be adopted, where no sampling of the nucleotide conformation database is needed. The motivation came from the hypothesis that the forces involved in the formation of the bps drive RNA folding and constrain the backbone bends and twists to adopt conformations that satisfy the base pairing arrangement. In other words, the backbone conformation is a consequence of base pairing.

The new RNA 3-D structure building engine positions only the actual rigid components of the nucleotides: the bases and phosphate groups. The coordinates of the interconnecting riboses are generated from an optimization process in constant time. The lengths of the bonds that link the phosphate groups to the ribose replaces the former O3′-P adjacency constraint during the backtracking. The absence of backbone sampling considerably reduces the size of the CSP search space, while simplifying the task of the user since no nucleotide conformation characteristics need to be input. Note, however, that constraints on the backbone can still be described and are checked.

3.3.4 Cycles of Interactions

The introduction of the spanning tree to generate RNA 3-D structures implies a conceptual pitfall. In the RNA graph, the structural information in the edges that are not covered by the spanning tree is not contributing to the building.

Take for example the construction of two-stacked Watson–Crick bps. One spanning tree would employ the two base pairing edges and only one stack edge. The solution structures could then include Watson–Crick bps that stack on one side only. User constraints need to be introduced to make sure the stack information of the dropped edge is satisfied. However, *ad hoc* user constraints to represent sophisticated geometrical concepts such as base stacking or pairing are difficult to define.

Lemieux and Major have designed a structure building approach that addresses cycles of base interactions to overcome this pitfall. They realize that successive applications of edge transformations in a cycle results in the identity matrix. Consequently, a solution to the cyclic structure building problem is defined by the assignment of a transformation to each edge in the RNA graph so that for each cyclic subgraph the product of the transformations is close to the identity matrix.

3.3.5 Probabilistic Search

Exhaustive searches for all valid RNA 3-D structures are useful to analyze the possible alternative folding of an RNA. However, sometimes only a single valid structure is desired rather than all possible ones. Recent works on *MC-Sym* have shown that a probabilistic search algorithm generates valid structures more rapidly and with an increased diversification rate than the deterministic backtracking. The probabilistic algorithm successively selects a transformation at random. If a partial construction is invalid, then a fixed size backtracking search is launched. The backtracking runs until the constraints are satisfied, or until a maximum number of backtracking steps is reached. In the former case, the random assignments resume to the next edge in the RNA spanning tree. In the latter case, the current valid substructure is lost and the probabilistic search restarts at the first edge.

Benchmark results indicated that the probabilistic approach accelerates the generation of valid RNA 3-D structures if the search space is increased up to a critical point. This particular feature of the probabilistic search allows us to efficiently explore fine-grained conformational spaces. Exhaustive exploration of a coarse-grained search space, or nonexhaustive exploration of a fine-grained search space, is always a choice the modeler can make.

3.3.6 Building by Fragments

As in many problems, the ''divide and conquer'' paradigm has proven useful in RNA 3-D structure building. The divide-and-conquer algorithm splits a complex problem in many smaller and simpler to resolve subproblems. The solutions of the smaller problems are then joined together to compose the solutions of the larger problem. RNA structures can be easily split into smaller fragments that can be modeled independently, and then the small models for each fragment can be merged to form the larger structure.

MC-Sym can manipulate a fragment in the same way it manipulates a single base, by selecting one base of the fragment to define its local frame as seen in Sect. 3.2.1. The fragment coordinates can either be preconstructed by *MC-Sym* modeling, or extracted from a structure database. Fragment building of RNA 3-D structures is a direct application of RNA 3-D motif searching (see Sect. 2.3). In Major's laboratory, different ways of fragmenting RNA graphs are studied. They will eventually put together their results to provide a database of RNA fragments that

will fit an automated fragmentation of any RNA 3-D graph.

Consider the example in Fig. 11. The sarcin/ricin RNA graph can be fragmented in five independent and cyclic subgraphs. Each cyclic fragment can be solved independently by the cyclic RNA 3-D structure building approach. The final structure is the result of merging the independent solutions by applying transformations that superimpose the common edges.

3.4 *MANIP*: Interactive Computer Graphics

An alternative to automated RNA 3-D structure building is to use interactive computer graphic systems, where the

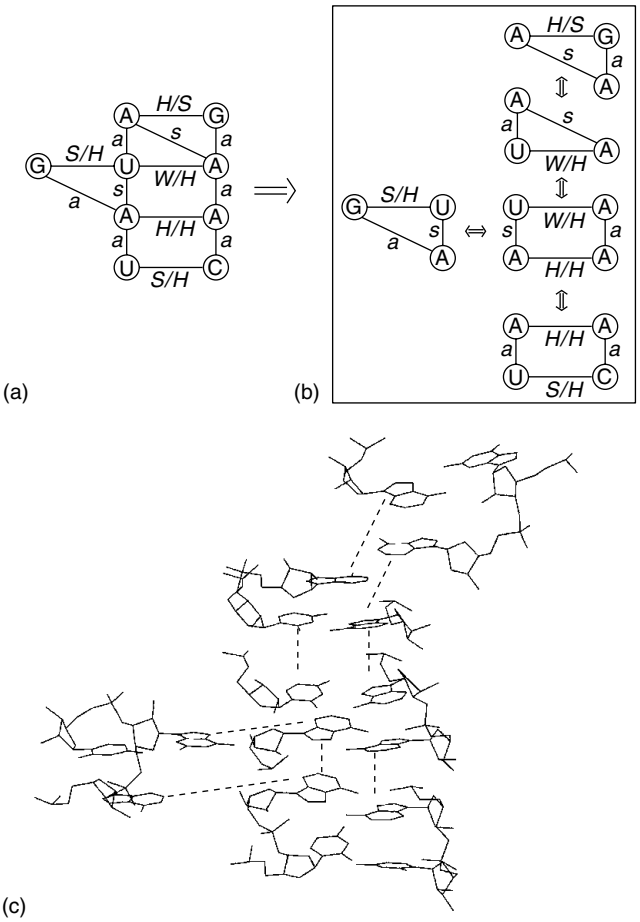

Fig. 11 Sarcin/ricin motif revisited. (a) RNA graph. See caption of Figure 8b. (b) Cyclic subgraphs. The fragmentation of the sarcin/ricin RNA graph results in five independent cyclic subgraphs. (c) 3-D structure. The independent results for each fragment are merged together to produce the motif 3-D structure. The dotted lines indicate the nucleotides shared by two fragments, and that need to be superimposed to construct the final structure.

user can interactively manipulate RNA structures and fragments in 3-D space. Such systems also allow the user to build and assemble RNA fragments in complete and larger RNA structures. Stereo chemical constraint and force fields are dynamically applied to limit the user to valid manipulations and buildings.

A popular system is *MANIP*, developed by Massire and Westhof. *MANIP*'s graphical interface gives the user the flexibility that is needed to create and move fragments by using the desktop keyboard and mouse, or more sophisticated input devices such as dials and wheels. The user's "artworks" are refined by applying integrated molecular mechanics minimization, here NUCLIN–NUCLSQ. Minimization ensures a correct stereochemistry at the nucleotide conformation level, removes the bad atomic contacts, and corrects the bad bond angles and torsions. The force fields implemented in NUCLIN–NUCLSQ was especially developed for RNAs.

The refinement step also allows for the identification of potential HBs and bps by matching their geometries to a database of known bps. Systems like *MANIP* are limited by the content of their database, here predefined fragments and bps. The major drawback of such interactive systems is the need for in-depth knowledge of RNA 3-D structure combined with strong experience in RNA 3-D modeling. But still, the *MANIP* system has proven useful in the context of sketch modeling to provide initial insights and starting points for further sharper modeling and structure determination projects.

ERNA-3D is another interactive system that was developed by Mueller and Brimacombe. It was applied to the modeling of the 3-D folding of the *Escherichia coli* 16S rRNA that fitted a 3-D electron microscopic map at a resolution of 20 Å.

4 Refinement

The structure building methods presented in Sect. 3 are mainly based on geometrical parameters and use rigid and discrete partitioning of RNA atomic structures. There is a need for further refinement of the resulting structures, and to fix the RNA internal geometry such as covalent bond lengths, angles, and torsions. Molecular dynamics fill this need.

The classical approach to simulate the molecular dynamics of RNA is to model at the atomic level the force fields that apply. This is achieved by developing an empirical model of potential energy function describing the known physical properties of RNA structures. The Newton's classical motion equations are applied and solved over discrete time steps from the evaluation of derivatives of the potential energy function. The equations can be solved by numerical optimization or heuristic methods. As shorter time steps are needed to obtain a reliable simulation, more steps need to be evaluated to reach energy minima. The input RNA 3-D structures of molecular dynamics need to be of good precision, which is not always possible due to the approximations made in modeling. Molecular dynamics can only be used as an RNA 3-D structure building procedure when a large number of precise constraints are known, such as to resolve NMR structures, and is rarely used as a modeling tool otherwise.

The critical part of a molecular dynamics simulation system lies in force field modeling. Three energetic interactions prime the force field: (1) a bonded interaction term, (2) a nonbonded charged interaction

term, and (3) a nonbonded noncharged interaction term. Bonded interactions result from distortions in covalently bonded atoms, and are measured by bond length, angle, and torsion variations from empirical data. Nonbonded charged interactions result from Coulomb electrostatic forces between charged atoms. Finally, a dispersion–repulsion force occurs between nonbonded and noncharged atoms by induced dipole–dipole interactions, and is often modeled by a Lennard–Jones potential, which is lightly attractive as two uncharged molecules approach from a distance, but is strongly repulsive when they are pushed close to each other.

Amber (assisted model building with energy refinement) is a widely used force field implementation. It was initially parameterized for proteins, but more recently a generalization has made it convenient for any organic molecule. The molecular dynamics simulation program *JUMNA* (JUnction Minimization of Nucleic Acids), has been developed specifically for nucleic acids. *JUMNA* has two additional terms to its potential energy function to restrain base pairing and stacking. Lavery and his colleagues have implemented a harmonic potential energy function to consider explicitly the geometrical properties of base stacking and pairing. The base center-to-center distances and angles are measured between the base normal vectors, which parameterize stacking interactions. HB lengths and the donor acceptor angle are used to parameterize base pairing interactions.

5 Applications

This section is dedicated to applications of computer modeling of RNA 3-D structure. Section 5.1 introduces applications that employed *MC-Sym*, whereas Sect. 5.2 discusses applications of *MANIP*. The applications in each subsection are introduced chronologically.

5.1 *MC-Sym*

5.1.1 Yeast tRNA-Phe (1993)

The classical benchmark of computer modeling of RNA 3-D structure is the yeast tRNA-Phe. In 1993, Major and coworkers demonstrated some capabilities of their computer modeling system *MC-Sym* by modeling the benchmark with great atomic precision. They generated 26 different structures sharing RMSD with the X-ray crystal structure from 3.1 to 3.8 Å, prior to their postprocessing refinement by energy minimization. They introduced other structural information that was available in the 1960s: the secondary structure, and the U8–A14, G9 = C56, G10–G45, U54–A58 bps. They also assumed stacking between the amino-acceptor and D-stems, as well as between the anticodon and T stems. The loops were modeled independently and only the best loop structures (smallest RMSD with the crystal) were kept and appended to the general construction. A key constraint to obtain L-shaped structures was bp U8–A14, as determined by UV irradiation cross-linking. The theoretical size of the search tree defined by the input of the tRNA constraints is 10^{26} nodes. The constraints pruned the search tree efficiently and only about 10^5 nodes were explored by the backtracking algorithm. In the 1960s, the most successful model was built by Levitt who proposed parallel coaxial stems (amino-acceptor stem and D-stem stack on each other and are positioned parallel to the anticodon stem and T stem that stack on each other)

rather than the typical L-shape of the crystal structure. The efficiency of the *MC-Sym* search was astonishing, and could be explained by the fact that a limited number of transformations were available, including a large fraction from the tRNA; the only large RNA structure at that time.

Nowadays, with the availability of many more high-resolution RNA structures, in particular the LSU, the transformation database (see Sect. 3.2.2) has grown to the 10^4 entries, ideal to test the new probabilistic version of the modeling program. Therefore, using the same input as in 1993, the probabilistic search method found 80 different 3-D structures exploring a search tree of 10^{38} nodes during seven days. The RMSD between the generated structures and the crystal structure range from 5.2 to 12.6 Å and were much higher than for those obtained by Major and coworkers in 1993. However, if the RMSD is evaluated among the stem regions only (loops removed), then the value range is 2.3 to 9.9 Å (see Fig. 12). Thus, the main structural differences with the 1993

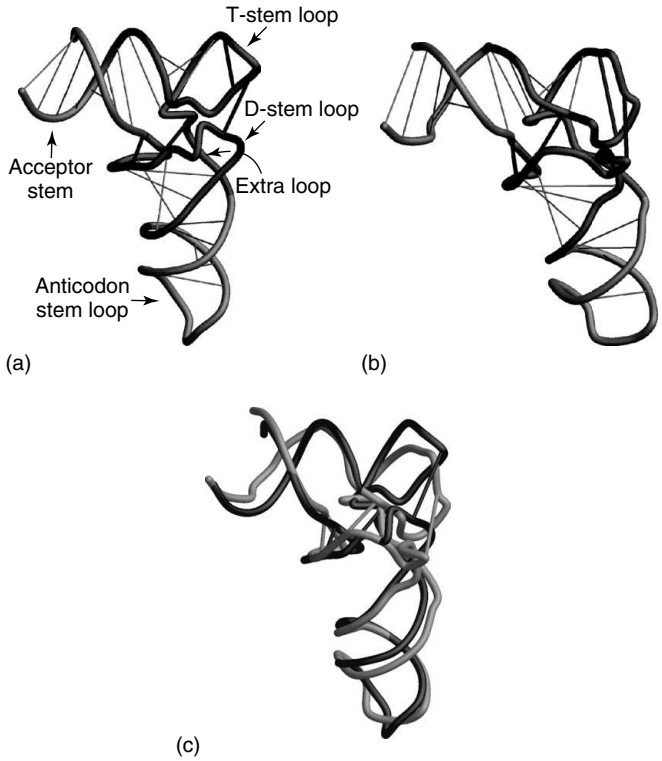

Fig. 12 Yeast tRNA-Phe. (a) Backbone representation of the crystal structure. The thin lines indicate secondary structure bps, and the thick lines indicate tertiary bps. (b) Backbone representation of the model, as generated by *MC-Sym* (probabilistic version). (c) Superimposition of the crystal structure and model. Dark backbone: crystal; light backbone: model. All atom but H in all nonloop nucleotide RMSD: 2.3 Å.

models are in the loops. No constraints were specified in the probabilistic search, whereas in the 1993 models, the loops were fine-modeled prior to the global search. The probabilistic search method found better solutions and generated a greater diversification of structures. Observations of the generated structures revealed that the base pairing between U8 and A14 is most represented among the tertiary interactions, supporting the 1993 claim that this base pairing is sufficient to determine the L-shaped tRNAs.

5.1.2 Ribonuclease P RNA (1996–1999)

Nolan in Pace's laboratory modeled the L14-P8-L18 (GNRA–helix–GNRA) junction in the RNase P RNA. The base pairing geometry linking the three fragments was inferred from aligning and comparing sequences of a large naturally occurring microbial population of RNase P RNA–encoding genes. Easterwood and Harvey extended the RNase P RNA modeling. In *E. coli*, they proposed structures of the 15/16 bulge, and in *Bacillus subtilis*, they built models of the binding between RNase P RNA P15 and a pre-tRNA. Schmitt applied the results of comparative sequence analysis and chemical modifications to generate 3-D structures of the RNase mitochondrial RNA processing (MRP). The modeled MRP RNA structure reveals two main structural domains, one highly conserved among all MRPs and RNase P RNAs, and the other only present in MRPs.

5.1.3 Hairpin Ribozyme (1999)

The hairpin ribozyme is a small catalytic RNA, which acts as an endonuclease that catalyzes a reversible sequence-specific cleavage reaction within a substrate RNA. Lambert in Major's laboratory initiated the modeling of the hairpin from a previously *MANIP* built 3-D model provided by Westhof and coworkers, as well as preliminary structural data provided by the laboratory of Burke. Preliminary structures generated by *MC-Sym* revealed the formation of a possible base triple (a single base simultaneously paired to two other bases) involving a nucleotide in the substrate that was considered to be immutable. The presence of the triple was verified and explained the immutability of the substrate base. In order to change the base in the substrate and to preserve the triple formation that was necessary to the activity, the two other nucleotides would have to be changed simultaneously to preserve the isostericity of the triple. Active hairpins were made by mutagenesis experiments that included isosteric triples. Other mutants that contained nonisosteric combinations were not active, confirming the hypothesis. Further theoretical and experimental modeling predicted the D-shaped conformation of the hairpin's substrate, as well as the complete hairpin structure and its precise chemical reaction mechanism. Recently, the same research team has determined a new active minimal hairpin by modifications and deletions of key helical elements within the two independent folding domains using cleavage activity experimental monitoring and *MC-Sym* modeling.

5.1.4 Leadzyme (1998–2001)

The leadzyme is an RNA molecule that is issued from *in vitro* selection of autocatalytic cleavage with lead ions using a library of yeast tRNA-Phe fragments. The leadzyme contains an asymmetric interior loop composed of six nucleotides: $C_1C_2A_3G_4$ on the 5′ side and G_7A_8 on 3′ side (see Fig. 13a). The leadzyme autocleaves in the presence of lead ions. Starting with the secondary structure and

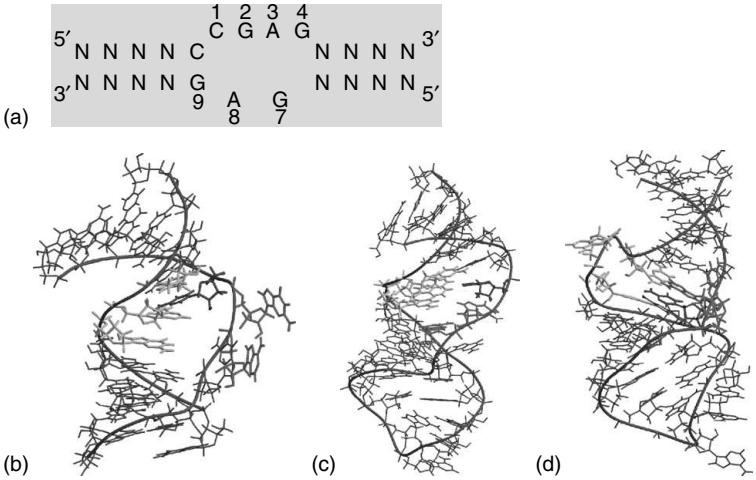

Fig. 13 Leadzyme. (a) Secondary structure. The nucleotides forming the catalytic site are numbered and colored. The scissile phosphate is the one of C_1 (red). G_2 and A_3 are not involved in base pairing (green). G_4 participates in the triple formation (black). The three nucleotides on the 3′ side of the catalytic core are colored yellow. (b) Crystal structure. (c) NMR structure. (d) Model. The colors defined in (a) apply to (b), (c), and (d). All atoms but H are shown. The phosphodiester chains are shown by a line tracing the P atoms. (See color plate p. xl.)

eight leadzyme variants (slightly mutated sequences), Lemieux and coworkers had first proposed an active conformation of the leadzyme that included C_1–A_8 and G_4–G_7 bps. They applied a modeling protocol based on the intersection of conformational space of functionally related RNA sequences. The protocol computes the intersection of all consistent 3-D structures of the active sequences, and then works by elimination under the assumption that all leadzyme sequences should have the same active conformation.

Chemical modification assays addressing the specific atomic groups involved in the base interactions predicted in the model were performed, and they confirmed base pairing involvement of three out of the four bases. None of the chemical groups on A_8 were found to be important to the catalytic activity of the leadzyme, whereas the chemical groups of C_1 normally involved in Watson–Crick interactions were found to be important. Consequently, a new Watson–Crick partner was needed for C_1. Interestingly, the predicted G_4–G_7 bp left the Watson–Crick groups of G_7 exposed to the interior loop, ready to form partnership with C_1. The base triple C_1–G_7–G_4 was thus proposed to be formed in a step of the cleavage activity, as its structure allows all atoms thought to be involved in the catalytic reaction in the right configuration for an SN2 catalytic reaction mechanism (see Fig. 14). David and coworkers then compared Lemieux and coworkers' 3-D model of the catalytic leadzyme with the X-ray crystal structure of Wedekind and McKay, and the NMR structure of Hoogstraten and coworkers (see Fig. 13). In the model, all catalytic core nucleotides are C3′-*endo anti*, except for the C_1 C2′-*endo anti* conformation. The crystal structure agrees on the

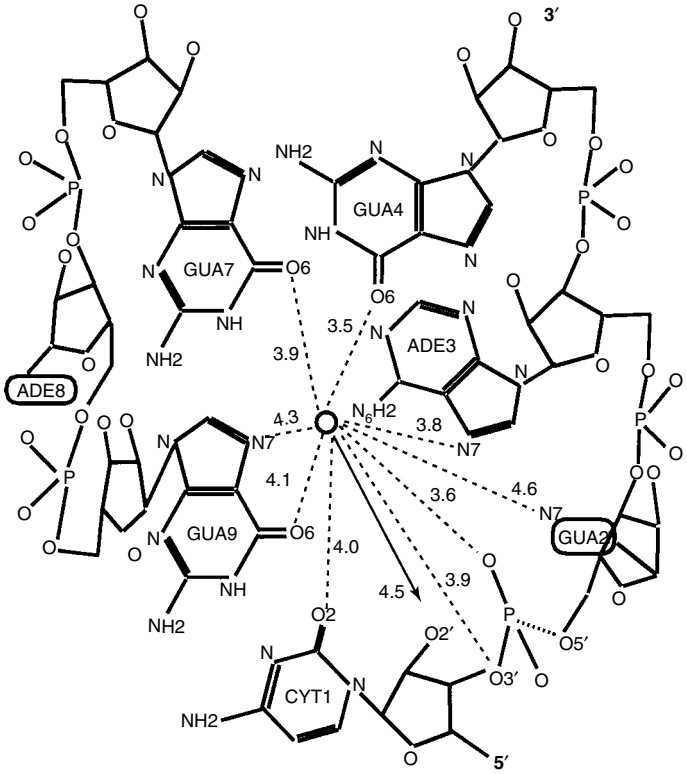

Fig. 14 Leadzyme catalytic core. The circle in the middle indicates the predicted position of the lead ion. The arrow points to the attacked 2′OH. The dotted lines indicate lead ion coordinations.

nucleotide conformations with the model, except for the G_4 C1′-*exo syn* conformation. The NMR structure disagrees with the crystal and model for all nuleotides on the 5′ side of the catalytic core: C_1 C3′-*endo anti*, G_2 C2′-*endo syn*, A_3 C2′-*exo anti*, and G_4 C1′-*exo anti*. The three structures agree on the stacking of A_3/G_9, as well as on the nonstacking between G_7 and A_8. The main difference in the base pairing between the model and the experimental structures is the base triple $C_1-G_7-G_4$, supported by chemical modification data. The experimental structures pair C_1 to A_8, even though chemical modification data did not identify any important chemical group for the catalytic activity on A_8, and did not show any base pairing between G_4 and G_7, in which chemical groups were shown to be important for the catalytic activity.

The model and crystal structures were found to be more stable to maintain their 3-D structures, as determined by molecular dynamics. A fitness function to evaluate SN2 propensity can be defined with the angle formed between O2′–P–O5′ and the distance between the O2′ and P atoms. An angle of 180° and a distance of 3 Å represent the structure with an optimal rate of transesterification. Again, the crystal structure and the

model maintain the SN2 configuration during molecular dynamics, although the theoretical model fit slightly better than the SN2 conformation.

5.1.5 *Escherichia Coli* 16S rRNA Fragments (2001)

Starting from the secondary structure, Dolan and coworkers modeled 58 different fragments of *E. coli* 16S rRNA using *MC-Sym*. They then added structural information inferred by chemical modification and covariation analysis. They assumed and favored the A-form helix conformation in nonhelical regions, and where no base pairing was inferred. The *MC-Sym* generated structures were refined by energy minimization using the *Insight II* suite of molecular modeling programs. The resulting fragment structures confirmed several structural inferences that were previously made in other rRNA studies, such as the presence of a central pseudoknot joining the three major domains of the ribosome's small subunit.

5.1.6 Prohead RNA (1998–2002)

A 174-nucleotide RNA has been shown to play an essential role in the DNA packaging of bacteriophage Φ29 in *B. subtilis*. From these 174 nucleotides, only a subsequence of 120 is necessary for efficient packaging. A preliminary secondary structure was proposed from comparative sequence analysis of sequences related to *B. subtilis* phages, and confirmed by directed mutagenesis experiments. Nucleotides 22 to 84 play an important role in prohead binding, as was determined by ribonuclease footprinting. The subunits were experimentally observed by electrophoresis gels and were shown to exist in hexamers. In order to further understand the specific packaging mechanism of this bacteriophage, *MC-Sym* was used to propose 3-D structures of this RNA.

The hexamer structure was determined to be circular, and composed of six copies of the same monomer structure. The monomers interact in the hexamer conformation by kissing nucleotides, as determined by comparative sequence analysis. By defining a transformation matrix, M, from an overlapping nucleotide in two consecutive monomers, Major and coworkers were able to select possible monomer structures that allowed for the formation of a cyclic hexamer, those satisfying the constraint $M^6 \approx I$. Other structure determination attempts include the application of electron microscopy of the hexamer, of X-ray crystallography of crystals adopting pentamer conformations, and of computer modeling of the dimer.

5.1.7 Red Clover Necrotic Mosaic Virus Bimolecular Complex (2004)

Guenther and coworkers at the North Carolina State University have studied the RNA–RNA structural interaction between the Red clover necrotic mosaic virus and the capsid protein subgenomic protomer that enables subgenomic RNA synthesis transactivation. This interaction was predicted by mutagenesis, but its precise 3-D structure was still unknown. Starting from NMR data of an *in vitro* RNA oligomer, they applied *MC-Sym* to solve the NMR constraints and to build 3-D models of the RNA–RNA interaction. They found a G–U wobble bp needs to be broken in the viral RNA structure to stabilize base pairing with the binding RNA.

5.2 *MANIP*

5.2.1 Group II Intron (2000)

Group II introns are known to recognize their 5′ exon by binding two exon

sequences (ESB1 and ESB2) by 6 bps respectively, and with two regions at the 3′ end of the 5′ exon (ISB1 and ISB2). Costa, Michel, and Westhof have modeled the complex between the exons, their binding sites, and the intron's domain V using structural data obtained from chemical footprinting, comparative sequence analysis, and the application of the *MANIP* modeling program. It was shown that reverse splicing of the group II intron is largely facilitated in the presence of a base pairing between the nucleotide 5′ of the ESB1 sequence (δ) and the 3′ exon (δ'). Applying computer modeling, Costa and her colleagues have proposed an alternative interaction pattern, where δ is base paired with the 5′ side of an interior loop within domain I, while the former δ', renamed IBS3 for clarity, was suggested to base pair with the 3′ side of the same interior loop (ESB3). Kinetic analysis showed that the new δ–δ' interaction is still needed to facilitate binding of the 5′ exon with the intron, while the ISB3–ESB3 interaction ensures an efficient exon ligation.

5.2.2 Hammerhead Ribozyme (2003)

The hammerhead ribozyme is a small RNA whose structure was extensively studied, mainly because of potential therapeutic properties. The hammerhead has a conserved catalytic core structured by the three-way junction of three helices, which confers its cleavage activity in high Mg^{2+} concentrations. Using site-directed mutagenesis data, Khvorova and coworkers identified additional conserved sequence elements outside the core that were necessary to initiate cleavage in low Mg^{2+} concentration. Different hammerhead sequences were in alignment showing that these critical nucleotides were present in the hammerhead's hairpin loops I and II, capping two of the core helices. Using this information and a crystal structure of the hammerhead, a 3-D model was built with *MANIP*.

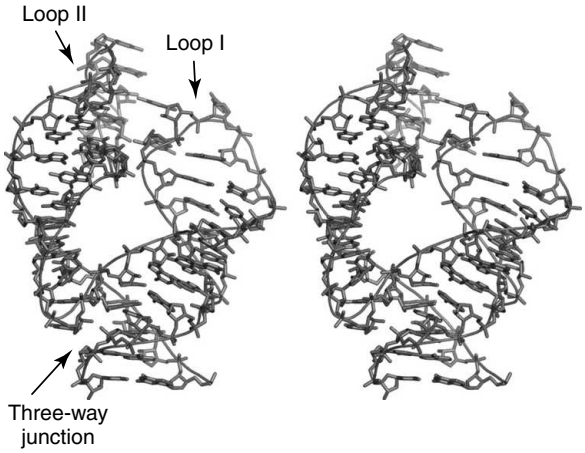

Fig. 15 Stereo view of a 3-D model of the hammerhead ribozyme. The model was generated by using *MANIP*. All atoms but H are shown. The phosphodiester chain is shown by a line tracing the P atoms. The modeled interaction between loop I and II can be seen. (Courtesy E. Westhof.)

The model showed H/H and S/S bps between the conserved nucleotides in loops I and II (see Fig. 15). They concluded that these noncanonical loop–loop interactions were necessary to activate the cleavage mechanism in low Mg^{2+} concentrations.

6 Perspectives

In the last 10 years, we have seen more modeling than ever, produced mainly from two RNA 3-D structure computer modeling systems: *MC-Sym* and *MANIP*. With *MC-Sym*, we are now close to a generation of computer programs that produce 3-D structures from a simple description of RNA structural data. In the near future, it is expected that RNA structure specialists will agree on more formalism to describe and unify all RNA abstractions unambiguously. Such formalisms will come from the result of multidisciplinary efforts involving computer scientists, biophysicists, and molecular biologists. As our knowledge of RNA 3-D structure increases, our ability to develop computer modeling systems to address the RNA theoretical flexibility will become better. After all, the success obtained with *MANIP* strongly suggests the existence of a precise and accurate formalism, in which automated modeling should produce high-precision models in efficient ways.

Keywords

Anosmia
Inability to detect environmental odors. Smell loss can reflect genetic or environmental factors, and can be transient or permanent.

Gene Repertoire
The members of a gene family or gene superfamily found in the genome of an organism that produce functional messenger RNA transcripts and functionally active gene products.

Odor Coding
The process by which the main olfactory system of vertebrates recognizes and differentiates among volatile chemicals to produce the perception of odor quality.

Olfaction
The sensory system responsible for smell and other aspects of flavor sensation, whose receptors are located within the superior or dorsal sectors of the nasal cavity.

Receptor
A specialized molecule on the surface or within the cytoplasm of a cell that serves as a recognition or ligand binding site for sensory stimuli, protein signals, neurotransmitters, steroids, antigens, antibodies, or other molecules found in the extracellular environment. After ligand binding, these activated receptors can either stimulate or inhibit a biochemical change in cellular activity.

Second Messenger
A short-lived chemical signal that is formed in the cytosol, relays and amplifies an externally derived message from a cell's surface to its interior, and subsequently stimulates or inhibits a biochemical change in cellular activity. Calcium ions, nitric oxide, cyclic AMP, cyclic GMP, and IP_3 can all function as second messengers in cells.

Smell
The psychological percept caused by activation of the olfactory system.

Olfactory receptor genes devoted to the sense of smell compose the largest multigene family in mammalian genomes. Although the number of receptor genes and related olfactory-specific genes vary in different species, up to 1% of the mammalian genome may be devoted exclusively to the sense of smell. This number reflects the importance of olfaction throughout vertebrate evolution, and the role of olfaction in maintaining a wide range of life-supporting activities, including feeding, nutrition, enhancement of gustatory responses, safety, predator/prey detection, and esthetics. In humans, ~400 different genes encode functional olfactory receptor proteins that localize to the ciliary membranes of ~6 000 000 receptor cells in the olfactory neuroepithelium only the visual system of vertebrates prossesses with more receptor cells.

In this chapter, we review basic aspects of olfactory system anatomy, expression of odorant receptors within sensory neurons, and pathways of mammalian and invertebrate olfactory transduction. We focus primarily on the main (i.e. nonvomeronasal organ) olfactory system of vertebrates. In particular, specific

attention is paid to the (1) chromosomal organization of olfactory receptor genes; (2) monogenic expression of olfactory receptor genes; (3) regulation of odorant receptor gene transcription within sensory neurons; (4) role of olfactory receptor gene expression in regulating the projection of functionally distinct olfactory sensory neurons from the olfactory epithelium to the olfactory bulb; (5) initial biochemical transduction events that include the molecular mechanisms responsible for stimulus transduction and generation of second messengers for signal amplification; and (6) microanatomy and function of olfactory bulb circuits. The plasticity of the olfactory system, as reflected by neurogenesis both within the olfactory neuroepithelium and the olfactory bulb is discussed in detail, as are a number of inherited and idiopathic human disorders associated with olfactory dysfunction in humans.

1 Introduction

Most organisms, whether they live in water, air, or in or on the ground, depend upon environmental chemicals for survival. For this reason, chemosensory systems have evolved in all animal phyla to detect such chemicals and to establish their meaning to the organism. Within the chordates – in particular the vertebrates – such systems have achieved great complexity, culminating in chemosensory systems within not only the general integument (e.g. free nerve endings within the skin that respond to chemical irritants), but numerous specialized receptor regions as well (e.g. taste buds). In mammals – the major focus of this chapter – the predominant intranasal chemosensory system is that of olfaction. Nearly all mammals, with the exception of whales and some other cetaceans, such as dolphins and porpoises, have a functional main olfactory system whose receptor cells are located in the nasal vault. The axons of these cells project through holes in the bony plate separating the nasal and brain cavities (termed the *foramina* of the cribriform plate of the ethmoid bone) to targets within the olfactory bulb, a complex ovoid structure located on the ventral surface of each frontal lobe on the dorsal side of the cribriform plate. These axons, which number in humans between 6 and 10 million, collectively comprise Cranial Nerve I (CN I).

A number of mammals also possess an ''accessory'' olfactory system whose neural projections are quite separate from those of the main olfactory system. The receptors of this system are found within a tube-like structure, termed the *vomeronasal organ*, located near the base of the nasal cavity. Openings into this organ occur, depending upon the species, either within the nasal cavity or through the vomer bone in the roof of the mouth. The receptor cells within this structure project axons to an ''accessory olfactory bulb'' (AOB) located behind the normal olfactory bulb. In rodents and ungulates, this system has been closely associated with reproductive processes. In a number of other vertebrates, including snakes, this system is involved in food finding and in both predator and prey identification. While a rudimentary vomeronasal sac is found in humans and some other Old World primates, these species have no AOB, and the vomeronasal organ has no neural connections to the brain. A diagram of the main and accessory

olfactory systems of the mouse is presented in Fig. 1.

The importance of olfaction to our own species is underappreciated, despite the fact that decreased smell function adversely influences the flavor of foods and beverages, places individuals at risk from hazards such as leaking natural gas, fire, and spoiled food, and significantly alters quality of life. Among 750 patients presenting to the University of Pennsylvania Smell and Taste Center with largely olfactory problems, more than 68% experienced altered quality of life, 46% described changes in appetite or body weight, and 56% reported influences in daily living or psychological well-being. Loss of smell, particularly when it occurs in adulthood, can result in significant psychological disruption and, in some cases, may even generate feelings of physical and social vulnerability and victimization. The

importance of this all-too-often underappreciated sensory system is reiterated by the consequences of its loss in those who depend on it for their livelihood (e.g. chefs, homemakers, firefighters, plumbers, fragrance and wine merchants, chemical plant workers, etc.).

In this chapter, we review advances in understanding olfactory function in mammals, emphasizing the signal transduction pathways, the evolution of odorant receptors, and olfactory coding at both the receptor and olfactory bulb level. Initially we summarize the basic anatomy and physiology of the mammalian olfactory system, with an emphasis on the olfactory epithelium, bulb, and cortex. Neurogenesis within the olfactory epithelium and bulb is then described. The next section examines early concepts of olfactory coding, followed by an elucidation of current views of mammalian odorant signal transduction. Included in this section are details of olfactory receptors, second messengers, and modes of terminating signal transduction. Subsequent sections describe olfactory receptor gene families, the organization and expression of mammalian olfactory genes, and the topographic organization of the olfactory pathways. The combinational system of odor representation and transcriptional regulation of olfactory receptor genes is then presented, followed by human clinical studies of gene-related olfactory disturbances.

2 Basic Structure of the Main Olfactory System

2.1 Olfactory Neuroepithelium

In humans, the receptors of the main olfactory system are located in the upper recesses of the nasal chambers within a layer of cells (termed the *olfactory neuroepithelium*) that lines the cribriform plate and sectors of the superior turbinate, middle turbinate, and septum Turbinates are shelf-like, cartilaginous structures that are covered by mucous membranes and protrude into the nasal airway to help warm, filter, and humidify inhaled air on its way to the lungs. In amphibia, the neuroepithelium is flat and planar, whereas in carnivores (e.g. dogs, cats), rodents, and many other mammals, it is distributed over a very convoluted surface dictated by the complexity of the turbinal folds that arise from the ethmoid bone. The number of ethmoidal turbinates differs among species, extending from one to three in primates to over a dozen in the spiny anteater (Echidna). A picture of the ethmoidal turbinates of the pig is shown in Fig. 2.

2.1.1 Cell Types

The olfactory neuroepithelium is comprised of a half dozen morphologically and biochemically distinct cell types, although additional classes of less well-defined microvilli-containing cells have been noted prenatally and postnatally (Fig. 3). The Microvilli are minute, brush-like, cylindrical processes on the cell surface that increase the surface size of the cell. The first cell type – the *bipolar sensory receptor neuron* – was first described by Schultze in the middle of the nineteenth century. This neuron contains a small (5–7 μm wide) cell body generally located within the lower two-thirds of the epithelium. Its single dendrite – that portion of the cell that is at the receiving end of information input – often takes a tortuous path within the mucosa around other dendrites, supporting cells, and adjacent receptor cell bodies

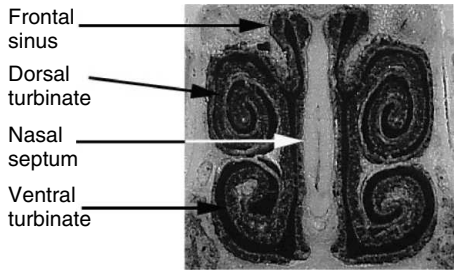

Fig. 2 Cross section of the nose of the adult pig. Note two sets of turbinates designated dorsal and ventral, the complex turbinal folds, and the thick nasal septum.

to reach the mocosal surface, where it extends, from a knob-like structure, odorant receptor-containing cilia into the mucus. Olfactory cilia contain the olfactory receptors and differ structurally from cilia in other segments of the respiratory tract, as described in detail later in this chapter. These cilia contain the olfactory receptors. A belt-like tight junctional complex attaches the dendrite to adjacent supporting cells at the apical surface, forming a transmembrane barrier characteristic of most epithelial cells. The receptor cell extends a single unmyelinated axon, which also takes a complex path to its target, in this case the olfactory bulb of the brain. The major neurotransmitter released from axon terminals of the olfactory receptor cells is glutamate.

The second cell type is the *supporting (sustentacular) cell*. These cells, which extend microvilli, rather than cilia, into the mucus layer, insulate the bipolar receptor cells from one another, and may help regulate the chemical composition of the mucus, secreting, for example, immunoglobulins into the mucus. Sustentacular cells also likely help to deactivate odorants, as well as to protect the epithelium from damage from xenobiotics. The supporting cells contain xenobiotic-metabolizing enzymes (e.g. cytochrome P-450s) that catabolize organic chemicals and other potentially damaging molecules that enter the nasal cavity. Such enzymes are also found within the acinar and duct cells of Bowman's glands, the major source of mucus in the olfactory epithelium.

The third cell type is the poorly understood *microvillar cell* located at the surface of the epithelium. Microvillar cells, which look similar to the so-called *brush cells* found throughout the upper and lower airways of many species, also have microvillae at their apical surfaces. While there has been suggestion that these cells extend axon-like processes to the olfactory bulb, convincing support for this notion is lacking. In the human, microvillar cells occur in about a 1 : 10 ratio with bipolar receptor cells. It seems unlikely that these cells play any direct role in chemosensory functioning, as *in vitro* patch clamping has failed to find any odorant-related responses.

The fourth cell type is the *cell that lines the Bowman's glands and ducts*, whereas the fifth and six cell types are the *globose (light) basal cell* and *horizontal (dark) basal cell* – cells located near the basement membrane from which most of the other cell types arise.

Recent data suggest that, under conditions of marked damage to the olfactory epithelium, the same type of basal cell, most likely the spherically shaped globose cell, has the potential for giving rise to neurons and nonneural cells, implying considerable multipotency. This population of stem cells is maintained in the

olfactory epithelium as these cells divide and give rise to new receptor neurons.

2.1.2 Receptor Cell Cilia

The bipolar receptor cells cilia differ from the cilia of the nonneuronal, respiratory epithelial cells, in being much longer and in lacking dynein arms required for intrinsic motility. Collectively, the surface area of the cilia is quite large, exceeding, for example, 7 m^2 in the German shepherd dog and 22 cm^2 in the human. This variation reflects not only the number of receptor cells but also the shape of the dendritic knob and the number and length of cilia that extend from it. The number of cilia per cell depends upon the species, with some species, such as the human, having from 10 to 30 cilia per cell, and others, such as the dog, having over a hundred per cell.

The olfactory cilia contain the cell surface receptors that interact with incoming odorants and have a $9 + 2$ microtubule fiber pattern similar to that found in other vertebrate cilia. Ultrastructural studies show that the cilia are devoid of endoplasmic reticulum (ER). Thus, little or no Ca^{2+} storage in internal membranes occurs in these cilia. This implies that, following odorant binding to receptors, depolarization of ciliary membranes occurs by cation influx from outside the cell.

2.1.3 Neurogenesis in the Neuroepithelium

Olfactory receptor cells, which are derived from ectoderm, the outermost layer of three primary germ layers of the embryo can regenerate to some degree after being damaged. This phenomenon, which was first observed in 1940, was in conflict with the dogma that neurons in the adult animal are irreplaceable, and suggested that the olfactory system may contain the key to producing neural regeneration in a variety of neural systems. In the 1960s, it was discovered that mitotic cells, young sensory cells, mature sensory cells, and dying cells coexist within the olfactory epithelium. This observation suggested that olfactory receptor cells were continually being replaced and were relatively short-lived. However, in the 1980s it was found that a number of olfactory receptor cells of rats reared in a pathogen-free environment survived for at least 12 months. This led to the concepts that (1) olfactory nerve cell turnover involves recently formed or immature receptor cells that fail to establish synaptic connections with the olfactory bulb; (2) environmental agents likely play an important role in dictating which elements of the receptor sheet become replaced; and (3) the rate of regeneration of olfactory receptor cells is not genetically predetermined. Today, questions still remain as to why metaplastic respiratory epithelium often replaces damaged regions of the olfactory epithelium and why, when such metaplasia occurs, the epithelium in that region may never convert back to olfactory epithelium. Nonetheless, studies employing toxic agents that damage the epithelium do find that the type of repair correlates with the degree or extent of the initial epithelial damage. Thus, when the basilar layer of the mucosa is completely damaged, replacement with a respiratory-like epithelium occurs. When the damage is not marked or the toxic insult is not sustained, regeneration, usually with fewer or irregularly arranged cells, occurs. The observation that improvement in olfactory function after cessation of chronic cigarette smoking occurs over a period of years and is dose-related suggests that either (1) turnover of the olfactory epithelial cell complement takes a much longer time

than previously supposed or (2) growth of olfactory epithelium into damaged areas is relatively slow and dependent on the extent of prior trauma, or both.

Numerous studies, some performed on olfactory epithelia grown in culture, have shown that homeostatic mechanisms regulate the development of olfactory receptor neurons so that the appropriate number of cells at each developmental stage is continuously maintained in the sensory epithelium. Such mechanisms include autocrine and paracrine signals, similar to those that function during embryonic development (When a factor, such as a hormone, is produced by the same cell that receives it, it is termed *an autocrine factor*. When such a factor is produced by a cell different than the one that receives it, it is termed *a paracrine factor*.). In addition, sensory neurons are trophically dependent on the olfactory bulb for their prolonged survival. Thus, when olfactory bulbs are lesioned in rodents, most olfactory neurons perish within a few weeks after lesioning. Such observations suggest that olfactory receptor neurons require trophic factors from the bulb at a critical stage in their development, and will not survive to maturity in the absence of such factors.

Growth factors, small proteins that bind to receptors on the surfaces of cells, are necessary for cell proliferation. A number of growth factors localize to the mammalian olfactory epithelium (Table 1). Among those implicated in olfactory epithelial neurogenesis are several members of the neurotrophin family and their cognate tropomyosin-related tyrosine kinase (Trk) receptors. Examples include brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), neurotrophin-4/5 (NT-4/5), and high-affinity nerve growth factor (NGF). NGF is a 130-kDa protein that is composed of five noncovalently linked subunits, and signals through TrkA receptors. This protein promotes and regulates the survival of neurons in the developing peripheral nervous system, and is produced by peripheral tissue for guidance and development of outgrowing sensory neurons. NGF is critical for both the survival and differentiation of sensory neurons, possibly by activation of the transcription factor called nuclear factor kappaB (NF-κB) or activation of receptor protein tyrosine kinases and activation of phosphatidylinositol 3-kinase (PI 3-kinase) (Nuclear factor-kappa B (NF-κB) transcription factors are required for regulating cell survival and differentiation, and are critical for the development and maintenance of the nervous system.) NGF also stimulates neurite outgrowth, and presumably stimulates axon formation in olfactory receptor neurons. Other receptor tyrosine kinases and their ligands may also participate in the regeneration of olfactory neurons within the adult rat olfactory mucosa. For example, NT-3 and NT-4/5 localize to the olfactory epithelium. NT-3 is the extracellular ligand for TrkC receptor, while BDNF or NT-4/5 can bind to, and activate, TrkB receptors. The targeted deletion of the NT-3 gene in mice increases the number of immature olfactory neurons in the epithelium. Interestingly, NGF immunoreactivity is upregulated in sensory neurons following bulbectomy.

Olfactory receptor neurons of the epithelium sequentially express TrkA, B, and C receptors during neuronal division, commitment, and differentiation. Upon binding neurotrophin ligands, Trk receptors undergo autophosphorylation, and create docking sites for signaling modules such as PI 3-kinases. Trk A is primarily detected in sparse populations of basal cells, and this receptor is highly expressed in differentiating neurons and immature

neurons. TrkC is highly expressed only in mature olfactory receptor neurons. Therefore, TrkA-positive basal cells function as neuronal precursor cells, and undergo mitosis to produce TrkB-positive immature neurons that, in turn, develop to become TrkC-positive mature neurons in the olfactory epithelium. Since the TrkC receptor is expressed in the last phase of development, growth factors associated

with this receptor may aid in the survival of olfactory neurons.

The neurotrophin NT-3 is another potential survival factor for olfactory sensory neurons. NT-3 localizes to discrete subsets of olfactory receptor neurons within the olfactory epithelium, as well as to the olfactory bulb. This trophic factor may function as a target-derived factor in olfactory receptor neuron survival and homeostasis, playing a role in coordinating proliferation, maturation, and survival of neurons essential to the maintenance of neuronal population homeostasis. *In vitro* studies have demonstrated that the addition of NT-3 to culture media prevents apoptosis of a select population of olfactory neurons.

Several fibroblast growth factors (FGFs) may also stimulate neurogenesis in the olfactory epithelium. FGFs comprise a large family of polypeptide growth factors, and the FGF family currently has over 20 distinct members. All FGFs bind with high affinity to at least one of four distinct receptor tyrosine kinases. The affinity of membrane-bound FGF receptors for ligands is determined by different sequences in the third extracellular immunoglobulin-like domain of the receptor, and occurs through alternative splicing of messenger RNA. FGF receptor-1 and FGF receptor-2 mRNA have been identified in the olfactory epithelium of rodents. Several reports suggest an effect of FGFs on neurogenesis in the olfactory epithelium. For example, FGF2 appears to have the largest proliferative effect on the olfactory epithelium although FGF1, FGF4, and FGF7 may also significantly increase cell proliferation.

2.2 Olfactory Bulb

In humans, the axons of receptor cells coalesce into 30 to 40 fascicles, termed the *olfactory fila*, formed by ensheathing glial cells. The fila leave the olfactory epithelium to traverse the cribriform plate and pia matter, and the axons form connections within the olfactory bulbs.

The olfactory bulbs are the first place where considerable synthesis of incoming sensory information occurs, and contain a remarkable number of neurotransmitters, including dopamine, GABA, and glutamate. Each bulb is composed of a number of cell types, including neurons, afferent and efferent nerve fibers, microglia, astrocytes, and blood vessels, all surrounded by a thin layer of pia-arachnoid cells. The cellular elements of the bulb are arranged in six concentric layers: the olfactory nerve layer (ONL), the glomerular layer (GL), the external plexiform layer (EPL), the mitral cell layer (MCL), the internal plexiform layer (IPL), and the granule cell layer (GCL). The GCL is the largest of these layers, making up about half the volume of the entire bulb (Fig. 4). Cells within this layer include axonless granule cells that extend a superficial process radially that ramifies and terminates among tufted or mitral cell dendrites within the EPL, and deep short-axon cells, whose axons extend into the EPL.

2.2.1 Olfactory Glomeruli

The first synapse of a CN I bipolar neuron occurs in one or two of the olfactory bulb's *glomeruli*, which are a defining feature of both vertebrate and invertebrate olfactory systems (Fig. 4(a–c)). Although the axons of the incoming olfactory neurons do not branch before reaching the glomeruli, once inside they branch repeatedly and make as many as 18 *en passant* and terminal bouton appositions. The glomeruli are an excellent example of the nervous system's grouping of neural elements and synapses into anatomically

defined modules, and are analogous to the multineuronal ''columns'' or ''barrels'' of the cerebral cortex. An olfactory bulb of young adult humans has ~8000 of these 50- to 200-μm structures, arranged in single or double layers within the GL. The development and maintenance of the glomeruli depend on trophic influences exerted by the receptor cells. With age, the number and integrity of the glomeruli greatly decrease, making them nearly absent in a number of persons over the age of 80 years. Considerable convergence of information occurs within the glomeruli, such that many more neurons enter than exit from each glomerulus. For example, in the rabbit, the convergence rates are 25 000 receptor cells onto 100 mitral cells and 500 tufted cells. Importantly, a genetically distinct receptor cell projects to only one or two glomeruli, and a given glomerulus receives most of its input from a restricted zone of the neuroepithelium, at least in the mouse. The topographical organization of glomeruli relative to receptor expression in neurons is discussed in detail in Sect. 7.

During odor stimulation, glutamate is released from axon terminals of olfactory receptor neurons onto the apical processes of mitral and tufted cells within the

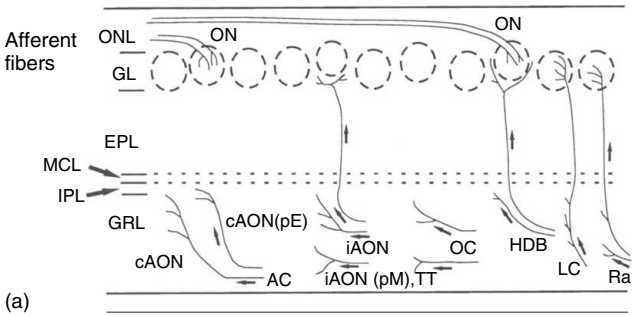

Fig. 4 Neural elements of the mammalian olfactory bulb, grouped according to subdivision into (a) afferent fibers, (b) principal cells, and (c) local interneurons. Diagrams based on various studies using the Golgi staining method and horse radish peroxidase (HRP) tracing. Fig. 4 (*Continued*)

glomeruli, as well as onto dendrites of periglomerular cells that function as interneurons. This glutamate is thought to bind to α-2-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) kaniate receptors on the dendrites of second-order neurons. As described in the next section, mitral and tufted cell activity is also influenced, usually in an inhibitory manner, by interactions with interneurons and centrifugal fibers primarily within the external plexiform layer of the bulb.

2.2.2 Centrifugal Inputs into the Bulb

The olfactory bulb's neural activity reflects influences from efferent as well as afferent processes. Among central structures that project axons or axon collaterals to the bulb are the pyramidal neurons of the olfactory cortex, the anterior olfactory nucleus, the nucleus of the horizontal limb of the diagonal band (a cholinergic center in the basal forebrain), the locus coeruleus, and the raphe nucleus (Fig. 4a, 8). Most of these structures send fibers to the granule cell layer of the bulb, and several, such as the locus coeruleus and the raphe nucleus, also send fibers to periglomerular regions, presumably inducing inhibitory responses on the primary output neurons of the bulb (i.e. the tufted and mitral cells). Although the exact function of such inputs is not known, they may participate in increasing sensitivity to selected odors based on bodily state (e.g. hunger, sexual arousal). Clearly, as noted in the next section, central brain structures have direct influences on the modulation of olfactory bulb output.

2.2.3 Olfactory Bulb Tuning of Afferent Signals

Dendritic activation of a particular subset of primary bulbar afferent neurons, that is, the mitral and tufted cells, is a selective process. Not all mitral or tufted cells reach the axon potential threshold at any moment in time. In some cases, this reflects too little odorant ligand and, hence, too little receptor cell activity to release an adequate amount of transmitter to induce an action potential. In other cases, the lack of firing of the mitral or tufted cell reflects inhibition from surrounding cells that raise the membrane potential. In this case, the cell cannot fire, even when synaptic input from the incoming receptor cells would, under other circumstances, be effective.

The basis of such tuning, which presumably sharpens contrasts between adjacent channels and leads ultimately to a synthesis of the odor construct, is complex, reflecting associations between local interneurons and dendritic processes of the mitral and tufted cells within and outside of the glomeruli. The activity of the local interneurons is regulated, in many cases, by afferent or efferent circuits, including the centrifugal processes noted in Sect. 2.2.2.

As shown in Fig. 4, the neural elements of the olfactory bulb can be grouped into three major categories: afferent fibers (receptor cell axons, centrifugal inputs), the principal output neurons (mitral and tufted cells), and local interneurons (e.g. granule cells, periglomerular cells). To understand the nature of such interactions, it is instructive to focus on the primary output neuron of the bulb, the ''mitral cell.'' Mitral cells typically have a single primary dendrite that has multiple ''tufts'' at their terminations within glomeruli. Such cells also have secondary dendrites that radiate horizontally (laterally) over long distances within the EPL. These secondary dendrites are linked by reciprocal synapses to dendritic spines on granule and periglomerular cells. Granule cells, which are GABAergic, form reciprocal dendrodendritic synapses with mitral and tufted cell secondary dendrites that connect with multiple glomeruli. Many of these cells receive the inputs from higher brain regions mentioned in Sect. 2.2.2. Periglomerular cells, which include both GABAergic and dopaminergic subtypes, largely mediate interactions among cells associated with the same glomerulus. They are a heterogeneous group of neurons that synapse, within the glomeruli, to the primary dendrites of both mitral and tufted cells, as well as to axons of receptor cells. These cells also make axodendritic connections outside of the glomeruli (Fig. 5).

The influence of granule cells upon mitral cells is profound. This reflects, in part, the fact that there are up to 100 granule cells synapsing on the dendrites of each mitral cell, and that each granule cell has 50 to 100 spines in those segments that enter into the EPL. As a result of such interactions, the mitral cell's resting potential is raised or lowered, increasing or decreasing its ability to produce an action potential and to influence surrounding bulbar regions. The net effect is that neuronal activity in one area of the bulb can produce a dampening effect on other areas of the bulb. In addition to shaping the odor activity pattern by enhancing or decreasing contrast across segments of the bulb, these circuits also play a critical role in establishing precise timing relationships between the spike activities of different output neurons, thereby increasing the efficiency of the temporal coding of odorants in the bulb.

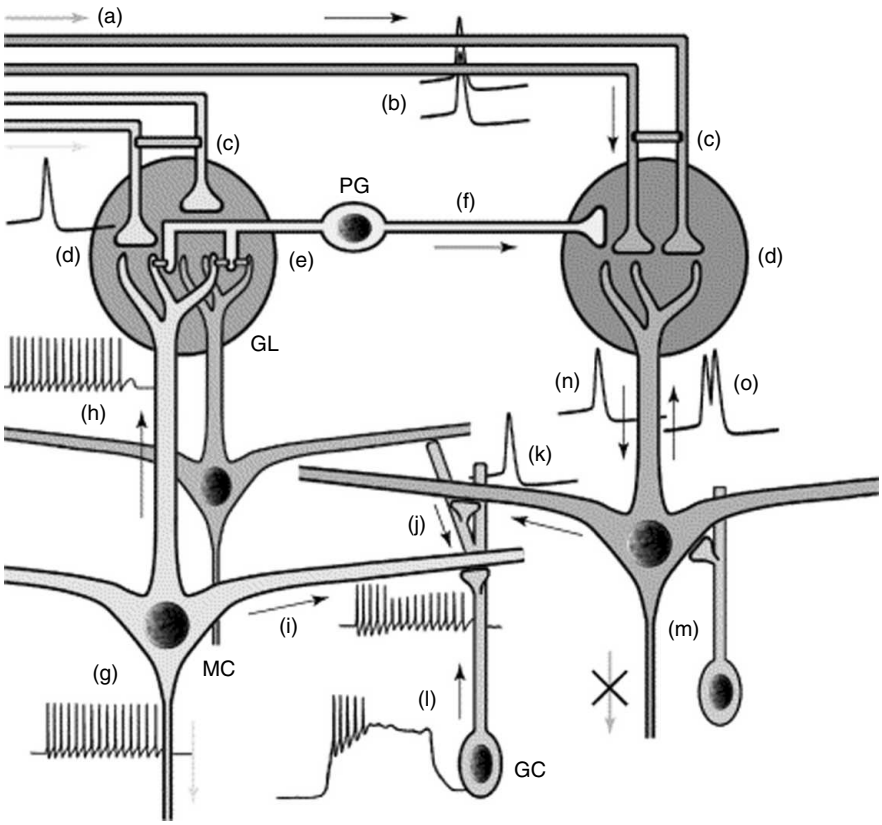

Fig. 5 Electrical signaling mechanisms in the olfactory bulb. (a) Action potentials propagate from olfactory receptor cells to glomeruli (GL), along axons segregated according to expressed odorant receptor genes (e.g. blue or red). Spikes may already be phase locked presynaptically (b) by ephaptic (point of contact where two or more nerve cell processes touch but do not form a typical synaptic contact), and (c) electrical coupling in nerve fascicles. (d) When action potentials invade olfactory nerve terminals, glutamate is released onto apical tufts of mitral cells (MC) and dendrites of periglomerular cells (PG). Tufts that share a glomerulus are coupled electrically by gap junctions, (e) perhaps through periglomerular cells, (f) which may relay timing information among glomeruli. (g) Glutamate evoked excitatory postsynaptic potentials in the tuft can depolarize the mitral soma and axon initial segment, which fires spike trains. (h) Spike output backpropagates up the primary dendrite to trigger glutamate release from tufts, and (e, f) coordinate firing in other mistral cells by electrical coupling. (I) Spikes also propagate laterally into secondary dendrites, in which they are subject to local inhibition by GABA release from granule cells (GC). (j) Lateral inhibition may spread locally among mitral cells through domains in the granule cell apical dendrite. (k) Domains are depolarized by glutamate released from other mitral cell dendrites with propagating spikes. (l) Strong depolarization drives ramped somatic spiking of granule cells, and these spikes back-propagate and release GABA throughout the granule dendrite. (m) Granule cell inhibition of the mitral soma can shift spike initiation to (n) the distal primary dendrite. (o) It can also veto mitral cell output, or generate compound waveforms composed of orthorhombic and back-propagating spikes. Reprinted from Lowe, G. (2003) Electrical signaling in the olfactory bulb. *Curr. Opin. Neurobiol*. **13**, 476–481. Copyright 2003 with permission from Elsevier. (See color plate p. xliii.)

2.2.4 Neurogenesis in the Bulb

It is of interest that cells arising in the subventricular zone of the brain regularly replace a number of neuronal populations within the olfactory bulbs of rodents. Although studies as early as 1912 found mitotic figures within the walls of the lateral ventricle, it was not until the 1960s that thymidine autoradiography confirmed the presence of DNA synthesis and the presence of proliferating cells within the subventricular zone, which lines, lining segments of the lateral ventricles. The progenitor cells that replenish interneurons of the olfactory bulb are localized in the anterior subventricular zone (aSVZ), a remnant of the lateral ganglionic eminence. Within this stem cell niche, cells with structural and molecular characteristics similar to astrocytes function as neural stem cells. These adult stem cells are thought to be derived from radial glial cells, and generate large numbers of neuroblasts. These migrating neuroblasts (see A cells in Fig. 6) express the neuron-specific class III β-tubulin (TUJ1), and the highly polysialated neural cell adhesion molecule (NCAM) that aids in migration. A subpopulation of these neuroblasts then undergoes restricted chain migration along a path known as *the rostral migratory stream*. This migration from the aSVZ terminates in the center of the olfactory bulb and occurs without guidance from radial glia or astrocytes. Reelin acts as a detachment signal for the migrating interneuron precursors, and this protein mediates chain dispersal. After release, differentiating neuroblasts migrate radially (outward) along glial processes, terminating within the periglomerular and granular layers where these neuroblasts mature into interneurons and form synaptic connections. Some of these new neurons become periglomerular cells that surround each glomerulus. A subpopulation of these new periglomerular cells known as juxtaglomerular neurons express enzymes such as tyrosine hydroxylase for synthesis of dopamine, and contain the inhibitory neurotransmitter γ-aminobutyric acid (GABA). In fact, over two-thirds of interneurons in the glomerular layer colocalize dopamine and GABA. Although the significance of neurogenesis of dopaminergic interneurons in the bulb is unclear, exposure of an animal to odorants has a significant effect on stimulating the expression of tyrosine hydroxylase, the rate-limiting enzyme of dopamine biosynthesis. Recent reports suggest that this neurotransmitter may inhibit olfactory sensory neuron activation of olfactory bulb neurons, including juxtaglomerular neurons, by olfactory receptor cells.

The migrating neuroblasts from the aSVZ also repopulate the granule cell layer where they form granular cells that integrate with existing neurons, including mitral cells. In NCAM-deficient mice that exhibit deficits in neuroblast migration to the bulb, the width of the granule cell layer is significantly reduced, and odor discrimination is impaired. Hence, new granule cells likely replace dying neurons, and granule cell activity is critical for normal odor discrimination. Presently, these migrating progenitor cells undergo differentiation by an unknown mechanism.

Factors that regulate neurogenesis in the SVZ are only now becoming apparent. One such factor that has received considerable study is *Vax*1, the ventral anterior homeobox containing gene 1. This gene product directs development of the basal forebrain, the visual system, and neuron turnover in the olfactory bulb. In particular, it regulates basal forebrain development by mediating

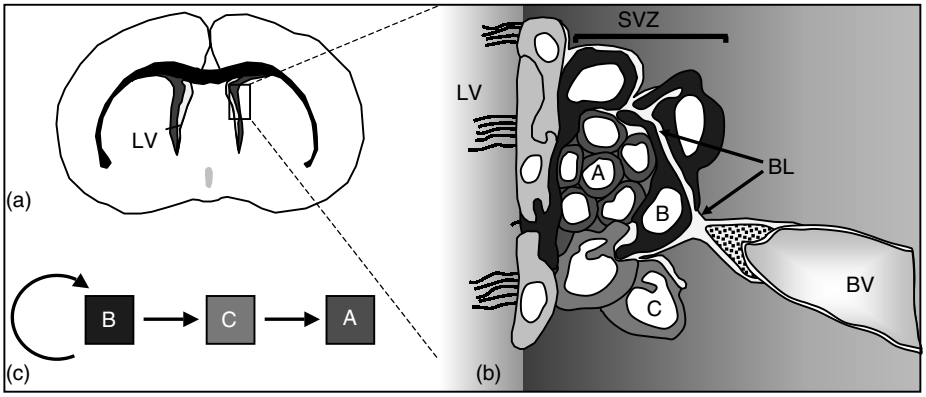

Fig. 6 Adult SVZ Neurogenesis in Rodents. (a) Coronal section through the adult mouse brain. Light blue shows the lateral ventricle (LV) space filled with cerebrospinal fluid. Boxed area is shown enlarged in B. (b) Architecture of the SVZ. B cells (dark blue) are the astrocytes that are stem cells of the SVZ, and also serve as niche cells. Some of the B cells contact the ventricle lumen and contain a single cilium (shown). C cells (green) are rapidly dividing transit-amplifying cells derived from the B cells. C cells give rise to A cells (red), neuroblasts that migrate to the olfactory bulb, where they become local interneurons. A blood vessel (BV, pink) is shown with a perivascular macrophage (dotted fill); a basal lamina (BL, yellow) extends from the BV and interdigitates extensively with the SVZ cells. Ciliated ependymal cells (gray) line the ventricle walls and have been shown to produce the organizer protein Noggin, which is important for this niche. Noggin, BMPs, Sonic hedgehog, Notch, TGFβ, ephrins, ephrin receptors, and vascular endothelial growth factor play roles in regulation of this neurogenic niche. (c) SVZ lineage. C cells can behave as stem cells under the influence of excess EGF signaling. Reprinted from Alvarez-Buylla, A., Lim, D.A. (2004) *Neuron*, **41**, 683–686. Copyright 2004 with permission from Elsevier. (See color plate p. xliv.)

axon guidance and major tract formation in the developing forebrain. *Vax*1 is an important regulator of SVZ organization and neural stem cell proliferation in rodents, where it is highly expressed in the developing and postnatal SVZ and rostral migratory stream. In *Vax1* mutant mice, the SVZ is significantly underdeveloped, and the differentiation and subsequent migration of precursor cells from the SVZ to the bulb is impaired. Since the SVZ supplies neurons to the bulb, olfactory bulbs in mutant mice are depleted of periglomerular neurons.

These stem cell phenomena, which are only now beginning to receive widespread attention within the chemical senses community, are of considerable significance, as they indicate that the plasticity of the olfactory system extends beyond the olfactory neuroepithelium. What role such regeneration plays in odor perception is not entirely clear, although it appears likely that it is an integral component of the olfactory process.

2.3 Olfactory Cortex

After leaving the olfactory bulb, the axons of primary projection neurons form the lateral olfactory tract and eventually synapse on structures collectively termed the *primary olfactory cortex* (Figs. 7 and 8). Although commonly divided into ''lateral'' and ''medial'' olfactory tracts in textbooks

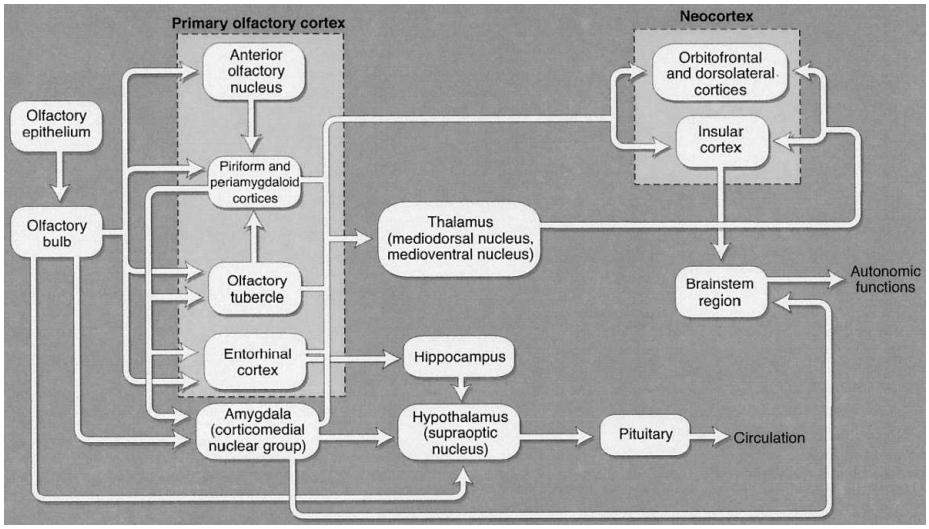

Fig. 7 Major afferent neural connections of the olfactory system. Structures common to both the olfactory and limbic systems include the olfactory tubercle, the entorhinal cortex, the amygdala, the hippocampus, and the hypothalamus. Although it is well established that the olfactory fibers project from the amygdala to the "feeding center" of the hypothalamus (especially the ventromedial and ventrolateral nuclei), it is unclear whether direct olfactohypothalamic routes exist in humans, as may be the case in some other vertebrates. Fig. 8 Major neural structures from which centrifugal fibers project to cells within the olfactory bulb. The anterior olfactory nucleus, locus coeruleus, and raphe nuclei are known to have projections to both olfactory bulbs. The other depicted structures are presumed to have primarily, if not solely, ipsilateral projections to the bulbs. Copyright © 2001 Richard L. Doty.

of anatomy, there is no meaningful medial olfactory tract in primates. In the human, the olfactory tract is relatively flat posteriorly and becomes the olfactory trigone, a small triangular area just rostral to the anterior perforated substance (so named because of the many small holes for blood vessels found throughout this region). It is generally believed that the main olfactory system is unique among sensory systems in sending fibers directly to cortical regions without synapsing in the thalamus.

Although definitions vary, the following structures are commonly considered primary olfactory cortex: (1) the anterior olfactory nucleus (AON), (2) the olfactory tubercle (poorly developed in humans), (3) the piriform cortex, (4) the anterior cortical nucleus of the amygdala, (5) the periamygdaloid complex, and (6) the rostral entorhinal cortex. In many species, the AON extends through the olfactory tract to the rostral part of the olfactory peduncle near the anterior perforated substance. This structure contains pyramidal cells whose dendrites receive synapses from mitral and tufted cells as well as from the contralateral AON (via the anterior commissure (AC)) and numerous central brain structures. The axons of its pyramidal cells project to ipsilateral bulb neurons (mainly granule cells) as well as to the contralateral AON, bulb, or rostral olfactory cortex via the AC. Although termed a nucleus, the AON has a cortical structure with subdivisions based on cellular architecture and connectional patterns.

Like the AON, the other components of the olfactory cortex have rich (and reciprocal) relations with a number of higher brain structures. One such structure is, the entorhinal cortex, which supplies afferent fibers along the entire length of the hippocampus, including the dentate gyrus. Because of these connections, the olfactory system has the most direct access of all sensory systems to the hippocampus. Extensive interactions occur between the cells comprising the superficial and deeper laminae of each component of the olfactory cortex as well as among the components themselves.

In humans, most of the projections from the mitral and tufted cells extend to the more rostral elements of the primary olfactory cortex. It is presently believed that specific sites within the bulb do not preferentially communicate with specific sites within the primary olfactory cortex; that is, no obvious point-to-point topography exists. Thus, small areas of the bulb can project to large areas of the olfactory cortex and vice versa. Among the brain regions that exhibit reciprocal connections with the olfactory cortex are the orbitofrontal cortex, the dorsomedial and submedial thalamic nuclei, the lateral hypothalamus, the amygdala, and the hippocampus. A major pathway from the olfactory cortex to the orbitofrontal cortex is via the mediodorsal nucleus of the thalamus.

3 Basic Structure of the Accessory Olfactory System

As noted in Sect. 1, receptors for the accessory olfactory system are found within the vomeronasal organ (VNO; Fig. 1). The accessory olfactory system consists of the VNO, the vomeronasal duct that opens into the VNO, seromucous glands that secrete into the lumen of the organ, paravomeronasal ganglia lying adjacent to the VNO neuroepithelium, blood vessels adjacent to the epithelium, vomeronasal nerve bundles, the vomeronasal cartilage,

the accessory olfactory bulbs, and central connections of the bulbs. The underdevelopment or lack of development of any one of these structures results in a nonfunctional VNO, as evidenced in a number of comparative studies. Surprisingly, considerable variability exists among a number of tetrapods in the presence of all elements of this system.

In most mammals that have been examined, the VNO is sexually dimorphic in the adult (larger in males than in females), reflecting the organizational action of sex steroids during the early postnatal period. The left and right VNOs are filled with fluid from vomeronasal glands, and are separated from one another by the nasal septum. The VNO neuroepithelium, like that of the main olfactory system, is comprised of neural, supporting, microvillar, and basal cells. As in the case of the main olfactory epithelium, chemicals are sensed by bipolar receptor cells embedded in the epithelium lining the medial concave side of the organ. Unlike the olfactory receptor cells, however, the VNO receptor cells of adult organisms lack cilia, instead containing microvillae, which harbor seven-transmembrane domain receptors (see Sect. 5.2 for a description of such receptors). The large blood vessels and sinuses along the lateral wall of the VNO, whose engorgement is controlled largely by the autonomic nervous system, can induce a pump-like action for bringing materials into the organ. Depending upon the species, entrance of chemicals into the VNO occurs via ducts from the anterior nasal or oral cavities. Stimulus access to the VNO is enhanced in some forms by distinct behaviors, such as the *flehmen* response – a characteristic lip curling and snorting behavior, in which the external nares are closed. This is frequently seen in cows, horses, deer, and sheep as the male samples the female's urine stream prior to estrus.

The axons from the VNO's sensory neurons project through the vomeronasal nerve, which typically runs along the base of the olfactory bulbs to the AOB, the first relay of the system. Recent data suggest the VNO system, unlike the main olfactory system, may be active only postnatally, at least in mice, since transneuronal tracers do not label mitral cells within the AOB prior to that time. Like the VNO proper, the AOB is sexually dimorphic, being larger in males than in females.

Dendritic processes of mitral cells within the AOB communicate, via glomeruli, with the axonal terminals of bipolar receptor cells. Axons of a given class of receptors converge onto numerous glomeruli with the AOB. The axons of the mitral cells project via a fiber bundle to the ''vomeronasal amygdala,'' consisting of the medial and posteromedial cortical amygdaloid nuclei and the nucleus of the accessory olfactory tract. The terminations within the medial nuclei are adjacent, but separate, from those from CN I projections, and this nucleus connects through the stria terminalis to the medial preoptic region of the hypothalamus.

Despite the fact, as mentioned earlier, that nearly all adult humans possess paired VNO-like structures at the base of the septum and paired VNO ducts ~15 to 20 mm from the posterior aspect of the external nares, this organ is nonfunctional. During embryogenesis, the human VNO develops a pseudostratified epithelium and loses receptor cells and their associated neural elements in the second trimester of pregnancy. The vestigial adult human VNO has a comparatively homogeneous epithelium along both its medial and lateral aspects, in contrast to the receptor-rich medial and receptor-free (but vascular rich)

lateral elements of the VNOs of other forms with functional systems. Adult human VNOs contain cilia (which are present only in the early embryonic stages of VNO development in most species) and short microvillae, unlike the elongated microvillae typical of other VNOs. Importantly, the transient receptor potential (Trp)-2 ion channel, required for transduction in the rodent VNO, is a nonfunctional pseudogene in humans. The lack of a VNO nerve and associated accessory olfactory bulb in postnatal humans is in stark contrast to the clearly delineated VNO nerves and accessory olfactory bulbs present in mammals with functioning VNOs, as described in more detail in Sect. 5.2.

4 Early Concepts of Olfactory Signal Transduction

Until the late 1970s, notions of olfactory coding largely reflected structure/activity associations, where activity was indexed by the psychological quality of the odorants to humans. Although physicochemical properties are much more quantitative than measures of odor quality, they too were found wanting. Since many physicochemical properties are highly correlated (e.g. solubility and molecular weight), equivalent prediction of odorant quality could be made using quite different physical parameters, limiting the explanatory value of any set of parameters. What was missing from such theories, in effect, were biological correlates and constraints. Among the more sophisticated of such theories was that proposed by Amoore, in which it was hypothesized that all odorant qualities arose from the relative activity of several ''primary odors'' in a manner analogous to the mixing of the color primaries of red, yellow, and blue to obtain spectral hues. The notion of primary odors is an ancient one, although Amoore brought to the fore better quantitative psychophysical assessment; that is, the use of threshold testing to establish the existence of the primaries. Thus, he proposed that some individuals have ''specific anosmias'' to certain odorants and that such anosmias are indicative of the involved primaries. Although some question the existence of specific anosmias (e.g. in many instances hyposmia, rather than anosmia, is present and repeated exposure to an odor can result in transforming a nonsmeller to a smeller), this approach to understanding underlying receptor mechanisms is logical and may still shed some light on the nature of the receptive elements of the main olfactory system. Examples of physicochemical-based theories of olfaction from 1870 to modern times are shown in Table 2.

5 The Modern Era of Olfactory Signal Transduction

During the last 25 years, monumental strides have been made in understanding the initial events of olfactory transduction. It is now known, as described in the following, serious that olfactory receptors are members of a well-identified family of receptors used in a number of sensory, neurotransmitter, and endocrine systems. The involved second messenger systems are well described, and topographic patterns of the convergence of receptor cells harboring individual receptor types are now well mapped, at least in mice.

Most odorants are relatively small (less than 300 Da), volatile, lipophilic molecules that are carried as vapors into the nose. The binding affinities for volatile odorants

are thought to be in the micromolar range. As described in detail later in this section, the smell produced by an odorant depends on its interaction with a specific receptor protein in the plasma membranes of olfactory cilia. Functional studies of amphibian and rodent olfactory receptors have demonstrated that multiple olfactory receptor proteins recognize individual odorants. Conversely, an individual olfactory receptor can recognize a variety of structurally different odorants, and may allow different response intensities to these odorants. These and other observations suggest that most olfactory receptors are broadly tuned, and have overlapping odor response profiles. This tuning allows for the identification and discrimination of a large number of different odorant molecules.

It is important to emphasize that odorants can exhibit a dual effect on olfactory receptor cells. They can either evoke an inward depolarizing (stimulatory) current, or they can suppress this current in such cells. Also, certain odorants may act as antagonists at the receptor level where they suppress the signaling initiated by structurally related compounds. For example, in the mouse, a derivative of isoeugenol has been shown to act as a potent competitive antagonist for the receptor that binds eugenol. This compound inhibits the physiological response of eugenol in HEK293 cells expressing mouse olfactory receptor ''EG.'' In potential support of such findings are human psychophysical studies that find the perceived intensity of an odorant mixture is often smaller than the sum of the intensities of its components.

Presently, no theory adequately explains how a specific odorant molecule causes the perception of a particular smell. A correlation between the chemical structure of an odorant, the odorant receptor combination it activates, and the perceived odor is not readily apparent. Structure–activity relationship studies suggest that the ligand binding site of an olfactory receptor can discriminate subtle differences in chemical structures of odorants, such as the D- and L-stereoisomers of carvone, while other receptors may be insensitive to large differences in molecular structure. Current evidence suggests that individual odorant receptors may recognize one or several specific structural motifs, or molecular features, that comprise an odorant molecule, and then map these different features to glomeruli in the olfactory bulb. Some theorists have suggested that olfactory receptors respond to intramolecular vibrations, perhaps via inelastic electron tunneling. Whatever the proximate basis of odorant receptor activation, it is clear that a unique combination of activated olfactory receptors and glomeruli encode the critical information passed on to higher brain centers that allow for the perception of an odor.

5.1 Odorant Binding Proteins

Odorant molecules are largely hydrophobic in nature. However, in many cases they must traverse the hydrophilic mucus layer before reaching the receptors of the olfactory cilia. To aid in this process, it has been hypothesized that many odorants bind to hydrophilic proteins that carry them through the aqueous media. Such proteins, termed *odorant binding proteins* (OBPs), have been identified within the nasal secretions at millimolar concentrations in a number of mammals, as well as in some invertebrates. To date, four types of vertebrate OBPs have been reported in mice, three in rabbits, and two in cattle.

The first such protein to be discovered, *odorant binding protein I* (OBP I), is a soluble homodimeric protein of 38 kDa that reportedly binds odorants with affinities in the micromolar range in a manner similar to retinol-binding protein in the visual system. The latter protein conveys retinol from the pigmented retinal epithelium to the rods and cones, where it is incorporated into rhodopsin. OBP I is a member of the lipocalin superfamily of proteins, a family that includes a large set of distantly related proteins that act as carriers for small, lipophilic molecules. This protein is highly concentrated in the tubuloacinar cells of the respiratory epithelium of the nasal mucosa. A second OBP was identified in 1991. This protein, known as *odorant binding protein II* (OBP II), is a secretory protein with DNA sequence homology to OBP I. The OBP II gene is expressed in the lateral nasal gland of rodents. OBP I and II are thought to interact with different classes of odorants.

Although it is generally accepted that OBPs are involved in odorant transport and perhaps in removal of odorants from the receptors, some recent studies are not entirely in accord with this notion. For example, expression studies have found high-affinity binding of unbound pig OBP I to a human olfactory receptor, an effect that would not be expected if OMB I is, in fact, a ligand carrier. Also, the crystal structure of bovine OBP I in complex with odorant molecules at a resolution of 2.0 Å was determined in 2004. No significant conformational changes were detected by structural comparison of crystal structures of unliganded and liganded OBP I, throwing into question whether, in fact, OBP I binds odors in a way analogous to retinol-binding protein in the retina.

5.2 Olfactory Receptors

Odorant molecules, carried in the inspired air into the nose, bind with olfactory receptors located on the cilia of receptor cells, initiating the transduction process. Parameters of airflow, including direction, velocity, and volume, determine the numbers of molecules that reach the receptors. In the human, from 5 to 15% of the inhaled airstream is diverted to the receptor region, depending upon the strength of sniffing and idiosyncratic aspects of nasal cavity anatomy, turbinate engorgement, and mucus secretion and rheology, the latter being affected by adrenergic, cholinergic, and peptidergic neural influences.

Hypothetising that the candidate odorant receptor proteins were members of a G-protein-coupled receptor (GPCR) superfamily, Linda Buck and Richard Axel in 1991, astutely employed a degenerate PCR strategy to amplify complementary DNA (cDNA) sequences from olfactory epithelial tissue encoding well-conserved GPCR amino acid motifs. Degenerate PCR was used to amplify odorant receptor sequences using primers that anneal to common GPCR motifs. This approach was highly successful, and the first 18 members of a novel GPCR gene family, the odorant receptor (OR) gene family, were identified. This landmark research was the impetus for the 2004 Nobel Prize in Medicine or Physiology.

Like other GPCR proteins, OR proteins are predicted to have seven transmembrane (TM) domains with a stereotyped topology (Fig. 9). OR proteins can be distinguished from other GPCR proteins on the basis of uniquely conserved amino acid motifs found at various positions in this predicted protein structure. The functions of these conserved amino acid motifs are

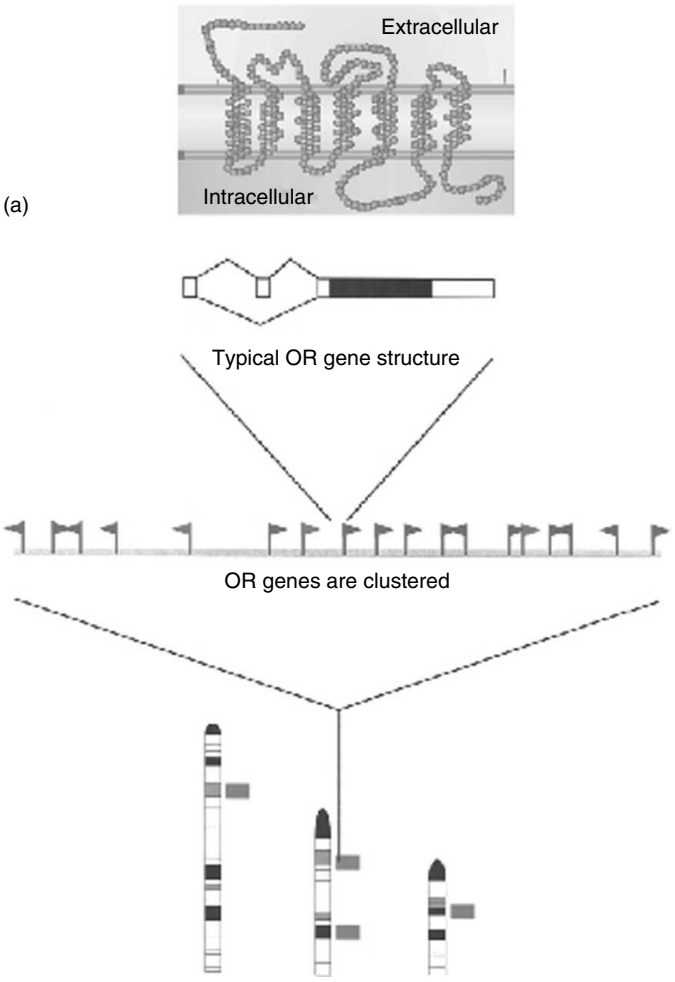

Fig. 9 OR genes. (a) Schematic drawing depicting the stereotyped structure of a GPCR protein, with seven membrane-spanning α-helices. Figure from Mombaerts, 2001. (b) Top: Gene structure and genome organization of OR genes. A typical OR gene consists of upstream noncoding exons that are commonly alternatively spliced, a single coding exon of approximately 1 kb (black), and a short 3′ untranslated region. Middle: OR genes are clustered in groups of 1 to over 100 genes (green arrows) and pseudogenes (red arrows) in both transcriptional orientations. Bottom: OR clusters are dispersed to more than 40 mouse and 100 human chromosomal locations. From Young, J.M., Trask, B.J. (2002) The sense of smell: genomics of vertebrate odorant receptors. *Hum. Mol. Genet.* **11**, 1153–60, by permission of Oxford University Press. (See color plate p. xlvi.)

not yet well understood, with the exception of the absolutely conserved ''DRY'' motif (aspartic acid, arginine, tyrosine consensus sequence) at the end of the third TM domain, which is required for activation and coupling of the G-protein.

Odorant receptor proteins probably interact with their odorant ligands using the internal TM domains (e.g. TM 3, 4, 5). This hypothesis stems from the characterization of analogous GPCR-ligand interactions, such as the β_2 adrenergic receptor-ligand interaction. It has also been noted that amino acid sequences within TM domains 3, 4, and 5 of odorant receptors are hypervariable in evolution, consistent with a role in interfacing with an enormous repertoire of varied odorants (Fig. 10a). Recently, a structural model of a specific OR protein was reported which was predictive with respect to experimentally established affinities to a panel of odorant ligands (Fig. 10b). In this model, residues in TM domains 3, 5, and 6 were predicted to be directly involved in odorant interactions. The receptor interacts with two different odorants with high affinity, and these interactions are hypothesized to involve different amino acid residues of TM domains. While this model awaits functional or structural studies for validation, these insights point to the possibility that OR proteins may not have fixed ligand pockets. The evolutionary success of the seven TM structure might be due to flexible ligand pockets, capable of many possible ligand interfaces involving different amino acid residues, which nevertheless transduce these diverse interactions into a common G-protein-mediated signaling effect in the cell.

The involvement of G-proteins in odorant transduction stemmed from studies in the early 1980s that reported activation of olfactory cilia by odorants required the presence of GTP. In 1987, a G-protein from an olfactory complementary DNA library was cloned that had 88% amino acid sequence identity to the stimulatory G-protein, G_s, and was strongly and almost exclusively expressed in olfactory cilia. This G-protein was designated $G\alpha_{olf}$ or G_{olf} and was found to be the predominant signaling G-protein in olfactory receptor cells. More recently, gene targeting has been used to examine the functional roles of the G-α subunit, G_{olf}, and type III adenylyl cyclase in olfactory signal transduction. Mice homozygous for a null mutation in G_{olf} exhibit a large reduction in the electrophysiological response of primary olfactory receptor neurons to a wide variety of odorants, verifying the important role of G_{olf} in mediating mammalian odorant signal transduction. Disruption of the gene for a critical subunit of type III adenylyl cyclase resulted in anosmia, as measured behaviorally and electrophysiologically, to all odorants tested, despite the presence of other adenylyl cyclases in the cilia. These results supported previous biochemical and genetic studies that implied that adenylyl cyclase and cAMP are essential for odorant signal transduction in vertebrates.

Although G-proteins other than G_{olf} (e.g. G_{i2} and G_o) have subsequently been identified in olfactory receptor neurons, they appear not to be involved in early transduction events, presumably assisting in such processes as axonal signal propagation, axon sorting, and target innervation. However, G_{i2} and G_o appear to play primary roles in vomeronasal sensory transduction. Interestingly, although G_{olf} was originally thought to be an olfactory-specific protein, we now know it is also expressed in the basal ganglia.

Relatively little is known about the expression of odorant receptor proteins in sensory neurons. Using polyclonal

antibodies raised against some odorant receptors, receptor protein visualization has been reported. Expression occurs as early as embryonic day 14, and is restricted to the cilia and dendritic knobs of receptor cells. However, such studies are not without their limitations. Thus, despite the general usefulness of antisera in biochemical and immunohistochemical studies, the extreme size of the odorant receptor gene family makes it very difficult to demonstrate the specificity of an antibody to a given receptor protein.

5.2.1 Identification of Ligand/Receptor Complexes

The inability to efficiently process, translocate, and functionally insert olfactory receptor proteins into the plasma membrane, as well as the low level of olfactory receptor expression in heterologous systems, has impeded the identification of most odorants with their cognate receptors. When expressed in cell lines, mammalian olfactory receptors generally exhibit improper receptor targeting to the plasma membrane, possibly due to improper folding and subsequent retention in the ER. Despite such difficulties, several investigators have overcome these problems and have identified a small number of ligand–receptor interactions.

The discovery of the first odorant/receptor pair occurred in 1997 in the nematode *Caenorhabditis elegans*, a worm that uses either a cGMP-gated or a Trp-gated channel for odorant signal transduction. The *odr-10* gene encodes a putative G-protein-coupled receptor whose expression is regulated by the *odr-7* gene product. In order to identify the function of *odr-10, odr-10* mutants were identified in a genetic screen. Then, mutant worms were exposed simultaneously to the volatile chemoattractants diacetyl and pyrazide. These two odors are sensed by AWA olfactory neurons in *C. elegans*. These worms showed defective chemotaxis only to the volatile odorant diacetyl (butanedione). A human cell line that

expresses the chemosensory receptor protein ODR-10 from *C. elegans* was found to display high ligand selectivity, and to exhibit a transient elevation in intracellular Ca^{2+} levels after addition of the odorant diacetyl. Untransfected cells did not show this response. These results implicated ODR-10 as the receptor for the odorant diacetyl.

In 1998, the first functional expression of an odorant receptor was made in a homologous system where adenovirus-mediated infection of neurons was used to identify which ligands would bind to an orphan olfactory receptor. Olfactory receptor I7 was expressed in mature sensory neurons of the rat olfactory epithelium by adenovirus-mediated gene transfer. For this study, recombinant adenovirus was prepared that encoded the I7 odorant receptor fused to green fluorescent protein (for localization), and introduced into the nasal cavity of rats. After adenovirus transfection of olfactory receptor neurons, *in vivo* electrophysiological recordings (i.e. changes in the summated extracellular field potential measured at the surface of the epithelium, termed the *electro-olfactogram or EOG*), were then used to functionally identify the expressed receptor and its ligands. These transfected sensory neurons responded to the compound *n*-octanol with elevated EOG responses. Smaller electrophysiological responses were found for structurally related aldehydes such as heptyl (C_7), nonyl (C_9), and decyl (C_{10}) aldehydes. However, negligible increases were detected for aldehydes with less than seven, or greater than 10, carbon atoms. In addition, an odorant with some antagonist activity was identified for receptor I7.

Calcium imaging has been employed to identify olfactory neurons that respond to odorants. Then the expressed receptor is identified after cloning. In some cases, a combination of gene targeting and Fura-2 Ca^{2+} imaging has been used to functionally analyze olfactory receptor neurons that express a defined olfactory receptor. For example, acetophenone and benzaldehyde were identified as agonists for mouse and rat M71 olfactory receptor in sensory neurons isolated from mice using a gene-targeted modification that caused coexpression of mouse olfactory receptor 71 and green fluorescent protein. In another experiment, a candidate mouse odorant receptor identified as MOR23, which is expressed in the olfactory epithelium and testis, was cloned from an olfactory neuron that displayed an odorant-induced increase in Ca^{2+}. Then, adenovirus-mediated expression of the cloned receptor gene was carried out in the olfactory epithelium, again with green fluorescent protein as a marker. Calcium imaging demonstrated that the adenovirus-infected neurons elicited Ca^{2+} entry upon stimulation with the odorant lyral. In addition, MOR23 also recognized compounds structurally similar to lyral. Therefore, these virally infected neurons elicited external Ca^{2+} entry when exposed to the same odorant that was originally used to identify the receptor gene.

5.3 Second Messengers

Second messengers are small intracellular molecules that change in concentration in response to environmental signals. Such change amplifies and conveys information inside the cell, which results in a metabolic change.

5.3.1 Adenosine 3′,5′-cyclic Phosphate (Cyclic AMP or cAMP)

A key signaling component of G-protein-coupled receptor activation is the enzyme

adenylyl cyclase, also known as *adenylate cyclase* (Fig. 11). During signal transduction, adenylyl cyclase functions as an effector that catalyzes the breakdown of cytosolic ATP into the second messenger 3′,5′-cyclic AMP, and pyrophosphate. This integral membrane protein contains twelve presumed TM domains, and two large cytoplasmic domains that form the catalytic component of the enzyme. It was discovered in the 1970s that the enzyme adenylyl cyclase, which is usually activated by a stimulatory G-protein, is highly active in olfactory tissue. Thus, adenylyl cyclase activity was found to increase, typically in the presence of GTP, in ciliary preparations following application of a number of olfactory ligands. Subsequent studies from the mid- to late-1980s reported a strong positive correlation between an odorant's ability to activate adenylyl cyclase activity in a frog ciliary preparation and both its perceived odor intensity to humans and the magnitude of the EOG response it produces in frog epithelia. These studies suggested that a functional role exists between the amount of activated adenylyl cyclase and intensity of odor perception, and that this relationship is highly conserved across a wide range of mammalian species. Such studies provided a mechanistic basis by which an odorant-stimulated increase in cyclic nucleotide concentration could lead to increased membrane conductance, to membrane depolarization, and generation of an action potential.

In the mid-1980s, the application of sophisticated patch-clamp techniques allowed for the study of voltage-gated membrane currents, single-channel recordings,

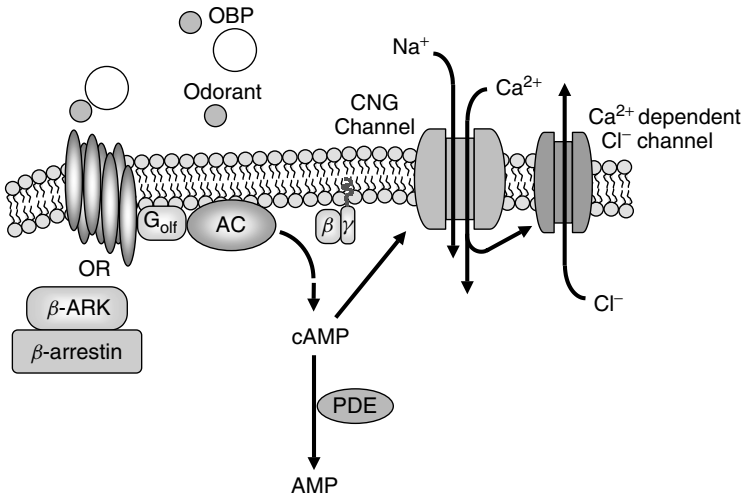

Fig. 11 Model of odorant signal transduction in mammals via the cyclic AMP pathway (see text for details). This signaling cascade mediates the initial steps in odor detection. Abbreviations: AC, adenylyl cyclase; AMP, 5′-adenosine monophosphate; β-ARK, beta-adrenergic receptor kinase; β-arrestin, beta-adrenergic receptor protein; $\beta\gamma$, beta and gamma subunits of GTP binding protein; cAMP, 3′5′-cyclic adenosine monophosphate; CNG channel, cyclic nucleotide-gated channel, G_{olf}, alpha subunit of olfactory GTP binding protein; OBP, odorant binding protein; OR, olfactory receptor; PDE, phosphodiesterase. and odorant-induced currents in both vertebrate and invertebrate olfactory receptor neurons. For example, using a patch-clamp procedure, a cAMP-gated channel in excised patches of cilia from toad olfactory neurons was identified in 1987. These ciliary patches contained a conductance that was gated directly not only by cAMP, but also by cGMP with a dissociation constant of 20 μM for cAMP and 5 μM for cGMP. At least three molecules of cyclic nucleotides must bind for activation of the membrane channel. Inhibitors of cAMP-gated channels quench odorant responses to this channel. In addition, cAMP, as measured by a rapid quench-flow technique, was rapidly and transiently produced in response to most odors, and some odorants appeared to directly suppress the cAMP-gated conductance by an unknown mechanism. These odorant-stimulated currents are similar to currents induced by flash photolysis of caged cAMP in olfactory neurons. Overall, these findings suggested a functional analogy to the cGMP-gated channel of vertebrate rod and cone photoreceptors. Cyclic nucleotide-gated (CNG) channel of mammalian olfactory neurons shares a 65% sequence identity with the cGMP channel of vertebrate photoreceptors.

Six distinct cyclic nucleotide-gated channel genes have been identified in mammals, and these genes are grouped into two subfamilies known as *CNGA,* which encodes the α-subunit of the channel, and *CNGB* which encodes the β-subunit. Each subunit contains six TM domain segments, a highly variable N-terminal domain, and a 130-amino acid domain at the C terminus. Mammalian olfactory receptor neurons express the three genes *CNGA2, CNGA4,* and *CNGB1b,* and vertebrate cyclic nucleotide-gated channels are heterotetramers that contain ion-conducting α-subunits, and modulatory β-subunits. Functional tetramers assemble by incorporating two subunits of CNGA2, and single subunits of CNGA4 and CNGB1b is highly permeable to Ca^{2+}. Ligand binding occurs at an intracellular cyclic nucleotide-binding domain in each subunit, causing a conformational change that opens the channel to cation influx. The binding domain is linked to the pore region by a ''C linker'' of approximately 90 amino acids in length. The olfactory cyclic nucleotide-gated channel is regulated by negative-feedback modulation by Ca^{2+}/calmodulin, since the binding of Ca^{2+}/calmodulin results in a decrease in the apparent binding affinity of cyclic nucleotide to these channels.

Recently, a targeted deletion of the cAMP-gated channel in mice showed that these mice were anosmic to all odorants tested when assessed by the electro-olfactogram (EOG). In addition, a mutation in a cyclic nucleotide-gated channel in *C. elegans* disrupted the response to selected odorants in these worms. Taken together, these studies suggest that the CNG channel is required for odorant signal transduction, and provide conclusive evidence that a CNG channel mediates most excitatory olfactory signal transduction in vertebrates such as mice. These results further suggest that cAMP (and possibly cGMP in a subset of sensory neurons) is the second messenger that mediates excitatory odorant signal transduction in mammals via a CNG channel.

The opening of the CNG channel allows an influx of Na^{+} and Ca^{2+} into the cell. As Ca^{2+} enters the cytoplasm of olfactory cilia through the channel, this cation activates a secondary depolarizing receptor current that mediates an outward Cl^{-} conductance in olfactory receptor neurons. Owing to the high Cl^{-} concentration within the

olfactory receptor neuron, this conductance causes an elevated reversal potential for Cl^-. This increases (depolarizes) the positive charge across the membrane so that an action potential is created. This second current thus amplifies the primary cationic current. The outward Cl^- current also allows a steep sigmoidal dependence on cAMP concentration in both rat and amphibian olfactory neurons. Finally, the sensitivity of this Cl^- current improves the signal-to-noise ratio of vertebrate odorant signal transduction. At present, the Ca^{2+}-dependent Cl^- channel that stimulates this conductance has not yet been identified at the molecular level in mammalian olfactory cilia.

5.3.2 Guanosine 3′,5′-cyclic Monophosphate (cyclic GMP or cGMP)

The fact that some olfactory receptor neurons do not express adenylyl cyclase suggests the existence of other transduction pathways. It is noteworthy that the CNG channel is responsive to cGMP, as well as cAMP, consistent with the hypothesis that cGMP may act as an alternative second messenger.

Two distinct classes of guanylyl cyclases have been identified that may regulate cGMP levels within the olfactory receptor cell: soluble guanylyl cyclase and membrane-bound guanylyl cyclase. The former is activated by gaseous messengers such as nitric oxide (NO) or carbon monoxide (CO), whereas the latter is activated by Ca^{2+} or specific extracellular ligands. Although cGMP is the primary second messenger in visual signal transduction, in olfaction this molecule has a relatively slow and sustained time course of activation. These results imply that cGMP does not play a role in initial olfactory signal transduction. The fact that both guanylyl cyclases are expressed in olfactory receptor cells suggests, however, a complex regulation of cGMP levels occurs within the olfactory receptor neurons.

Soluble guanylyl cyclase is activated by gaseous molecules after binding to the heme iron of protoporphyrin IX, which is a heme oxygenase (HO) inhibitor. NO and CO are generated by nitric oxide synthase (NOS) and heme oxygenase (HO), respectively. NOS most likely plays a role in the development of olfactory receptor cells, since it is expressed primarily in the embryo and is significantly reduced postnatally. In contrast, marked expression of HO only occurs postnatally, suggesting it plays a role in mature receptor neurons. HO-2, one of the two known forms of HO, is highly expressed in mature olfactory neurons, as well as in the outermost (neuronal) and innermost (granule cell) layers of the olfactory bulb. Odorant-induced increases in cGMP levels in the receptor cells are inhibited by Zn protoporphyrin IX, but not by an NOS inhibitor. However, since inhibition of HO does not completely deplete cGMP within the olfactory receptor cells, membrane-bound guanylyl cyclases likely contribute to the production of cGMP.

Considerable evidence suggests that olfactory receptor neurons contain multiple cGMP pathways that mediate both delayed and sustained cGMP odor-induced responses. At least two membrane-bound guanylyl cyclases, a low K_m and a high K_m isoform, have been found in rat olfactory cilia. Since elevation in ciliary cGMP occurs in a Ca^{2+}-dependent manner, and intracellular Ca^{2+} fluctuates in response to odorants, a Ca^{2+}-binding protein, such as guanylyl cyclase activating protein (GCAP), has been hypothesized to regulate particulate guanylyl cyclase within olfactory receptors. A similar pathway occurs in the visual transduction pathway.

Support for this hypothesis comes from immunohistochemical studies that find GCAP1 to be localized to olfactory cilia and to regulate odorant-induced cGMP responses in a Ca^{2+}-dependent manner.

A subset of olfactory neurons that expresses guanylyl cyclase also expresses the cyclic GMP-stimulated phosphodiesterase 2(PDE2), an enzyme that catalyzes the breakdown of cyclic GMP to GMP in these cells. Interestingly, a subunit of the CNG channel previously found in cone photoreceptors is also present in these neurons, suggesting that they may contain a unique CNG channel. Neurons that express PDE2 and membrane-bound guanylyl cyclase D (an olfactory-specific cyclase), are thought to project to a distinct group of glomeruli, localized in the posterior aspects of the olfactory bulb that are similar in appearance to ''necklace glomeruli.'' Necklace glomeruli are important because these structures are a subset of ''atypical'' glomeruli that receive heavy cholinergic innervation, and may function in mother–infant interactions. Thus, selective compartmentalization of different phosphodiesterases and cyclases is involved in the regulation of odorant signal transduction in olfactory neurons. This selective compartmentalization may modulate the sensitivity of a subpopulation of sensory neurons to specific odorants.

It would appear that cGMP and cAMP produce distinctly different Ca^{2+} signaling kinetics and different cytosolic concentrations for CNG channel activation. Thus, cGMP reaches significantly lower levels in olfactory receptor neurons when compared to cAMP. These differences affect the rate and amount of cation influx into the cytosol of olfactory neurons. This influx may occur through a common CNG channel, or through functionally similar CNG channels with different subunit compositions. The second messenger signal is transient in the case of cAMP, and is more persistent in the case of cGMP. cGMP may thus participate in long-term cellular events in vertebrate olfactory receptor neurons such as desensitization, sensory adaptation, or neuronal activity-dependent transcription.

5.3.3 Inositol-1,4,5-trisphosphate (IP_3)

The PI signaling pathway generates the second messengers IP_3 and (1,2)-diacylglycerol (DAG) by hydrolysis of the membrane lipid phosphatidyl inositol 4,5-bisphosphate via cell surface receptors that couple to stimulatory G-proteins such as $G\alpha_q/G\alpha_{11}$, which then activate phospholipase C-β isoenzymes. DAG activates protein kinase C isoforms, while IP_3 binds to a membrane-bound tetrameric receptor/channel. The IP_3 receptor/channel is composed of a family of structurally related proteins with both distinct and overlapping tissue distributions. Upon binding of IP_3, this receptor/channel stimulates the transient release of Ca^{2+} from nonmitochondrial internal membrane stores (Fig. 12).

IP_3 receptors are highly enriched in ER membranes and sarcoplasmic reticulum membranes of muscle cells. Since odorant signal transduction occurs in cilia, and olfactory cilia contain no ER for Ca^{2+} storage and release, an IP_3 pathway in olfactory neurons, if indeed present, must utilize a plasma membrane IP_3 receptor. Therefore, Ca^{2+} influx would have to occur by this mechanism.

Although IP_3 has been implicated in the odorant response of both vertebrates and invertebrates, its role in mammalian olfactory transduction is controversial. The weight of the evidence suggests that IP_3 is not involved in the initial steps in mammalian odorant signal transduction. A plasma membrane IP_3 receptor/channel,

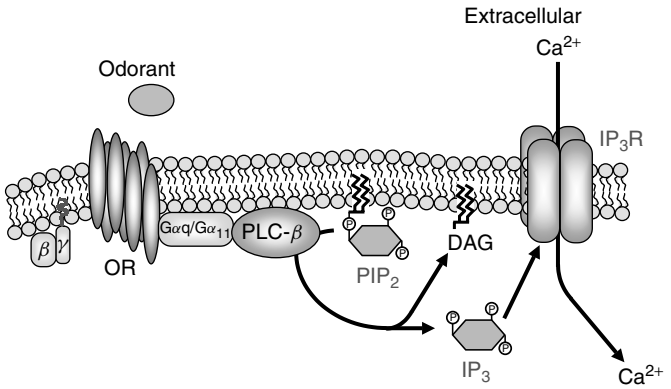

Fig. 12 Model of odorant signal transduction in invertebrates via the IP_3 pathway (see text for details). as well as a PI 3-kinase, is involved in odor transduction in the lobster, where considerable research has been carried out. In this crustacean, the olfactory organ consists of an array of hairlike sensilla located on the antennae. Each of these sensilla contain from two to several hundred primary olfactory receptor neurons that are easily recorded electrophysiologically.

In ''cultured'' lobster olfactory receptor neurons, IP_3 selectively evokes an excitatory current and directly activates two types of channels. Furthermore, odors can activate dual signal transduction pathways in lobster antennules where they both stimulate and inhibit the same olfactory neuron. Both cAMP and IP_3 levels are increased by odor stimulation in the outer dendritic membranes, where IP_3 activates stimulatory current, and cAMP activates the inhibitory current. When IP_3 and cAMP are applied to the inner face of cell-free patches of the outer dendritic membrane of lobster olfactory receptor neurons, both second messenger-gated plasma membrane channels are found in the same patch. In accord with these observations, IP_3 receptors and the PLC-β enzyme localize to the outer dendrites of lobsters, where PLC-β associates with G-proteins in response to odorants.

One possible target of this PI pathway is a Na^+-gated nonselective cation channel that generates a large component of the depolarizing receptor potential. Pharmacological studies have suggested that this Na^+-gated channel in lobsters may belong to the Trp family of plasma membrane receptors, conceivably similar to those reported in *C. elegans* Trp channels are Ca^{2+}-permeable channels, which have been proposed to function as store-operated channels in a variety of cell types in the presence of Na^+. Increased Ca^{2+} levels activate this nonselective cation channel. In addition, this Na^+-gated channel is modulated by addition of exogenous phosphoinositides in cell-free membrane

patches. In such neurons, this plasma membrane channel may amplify the olfactory receptor current.

5.4 Signal Termination and Desensitization

A number of processes are involved in signal termination and desensitization. Such processes include (1) phosphodiesterase action to break down cyclic nucleotides, as previously mentioned for cGMP, (2) phosphorylation of receptors with occupied ligand binding sites, (3) modulation of CNG channels, and (4) conversion into derivatives that do not function as second messengers.

The relative amount of cyclic nucleotide in an olfactory neuron is dependent on both the synthesis and breakdown of that second messenger. Thus, a critical process for olfactory transduction is termination of the odorant-induced signal in the receptor cells. In order to terminate the signal, a rapid decline in cAMP or cGMP formation occurs after odorant stimulation. This decline is catalyzed by cyclic nucleotide phosphodiesterases, which are responsible for the hydrolysis of both cAMP and cGMP to pyrophosphate. At present, three different phosphodiesterases have been identified in olfactory neurons. Of these three enzymes, two phosphodiesterases regulate the hydrolysis of cAMP to 5′-AMP in olfactory cilia for signal termination. A Ca^{2+}/calmodulin-dependent phosphodiesterase IC (PDE1C2), and a Ca^{2+}/calmodulin-independent high-affinity phosphodiesterase (PDE4A) specific for cAMP are both expressed at high levels in many olfactory neurons, with the high-affinity PDE4A being highly expressed in axons.

Many G-protein-coupled receptors show decreased ability to couple to G-proteins after prolonged agonist stimulation, a phenomenon known as *agonist-mediated desensitization*. G-protein-coupled TM receptors, and second messenger-dependent kinases may be involved in this desensitization process. This desensitization is initiated by receptor phosphorylation from G-protein-coupled receptor kinases that function to uncouple the olfactory receptor from its stimulatory G-protein. The phosphorylation and subsequent desensitization of olfactory receptors may occur by a specific receptor kinase named *β-adrenergic receptor kinase* (β-ARK). β-ARK is a heparin-sensitive serine–threonine kinase involved in homologous desensitization of G-protein-coupled receptors. However, the complete quenching of odorant signal transduction at the receptor level may further require binding of the protein cofactor β-arrestin to the phosphorylated olfactory receptor. The binding of β-arrestin results in uncoupling of the receptor from its stimulatory G-protein, and inhibition of cAMP formation. Isoforms of β-adrenergic receptor kinase and β-arrestin have been localized to olfactory neurons, but their function has not yet been demonstrated.

In olfactory neurons, the second messenger-dependent kinase involved in desensitization could also include protein kinase A, which is a serine–threonine kinase that requires cAMP for activation. In olfactory tissue, antagonists of protein kinase A prolong the production of cAMP by odorants. Although odorant-induced phosphorylation of ciliary proteins by protein kinase A has been demonstrated in olfactory tissue, the phosphorylated proteins have not yet been identified. Therefore, some cAMP that is formed in response to odorant stimulation may activate a negative-feedback pathway that

may inhibit the odorant response by phosphorylating specific target proteins.

Another mechanism for desensitization involves the CNG channel, where modulation of cAMP sensitivity of the olfactory CNG channel by Ca^{2+}/calmodulin occurs. When Ca^{2+} ions enter the olfactory cilia through the opened CNG channel, these cations mediate decreased responsivity of the sensory response by providing a negative-feedback signal that modulates the olfactory signal transduction machinery. One important mechanism for this rapid decline in sensitivity to odors is the Ca^{2+}/calmodulin-mediated reduction in cAMP sensitivity of the CNG channel. The modulatory CNGA4 subunit of the channel is thought to accelerate the Ca^{2+}-mediated negative feedback in olfactory signaling, and may allow rapid adaptation in the vertebrate olfactory system. When this gene is deleted, deficiencies in Ca^{2+}/calmodulin-dependent inhibition of the CNG channel occur. This inhibition results in a reduction in adaptation of odor-induced responses in the olfactory neurons. For example, channels in excised membrane patches from the null mouse exhibited slower Ca^{2+}/calmodulin-mediated channel desensitization.

Desensitization may also occur via PI 3-kinase, an enzyme that phosphorylates inusitol phospholipids in the plasma membrane. These lipids then become docking sites for other intracellular signaling proteins. In dissociated rat olfactory receptor neurons, the blocking of PI 3-kinase activity increased an odorant-evoked, cyclic nucleotide-dependent elevation of cytosolic Ca^{2+}. This finding suggests that 3-phosphoinositide signaling may inhibit cyclic nucleotide-dependent excitation of the cells during vertebrate olfactory transduction. Whether this signal transduction pathway acts in concert with the cAMP pathway, or functions to desensitize the cAMP pathway in olfactory receptor neurons, remains to be determined (Fig. 11).

Finally, the second messenger IP_3, is inactivated when this molecule is converted into derivatives that do not open, IP_3 receptor/cannels IP_3 may be converted to inositol by phosphates or phosphorylated to 1,3,4,5-tetrakis phosphate which is then converted to inositol.

6
Olfactory System Receptor Gene Repertoires in Vertebrates

6.1
Main Olfactory System

The biological challenges of the olfactory system are similar to those of the immune system. Both systems must be able to recognize a broad range of environmental chemicals, even ones that the animal has never before been exposed to in its evolutionary past. The breadth and adaptability in antigen recognition of the immune system is based on an elegant combinatorial strategy: a limited number of gene segments are recombined to generate an enormous diversity of antigen receptor combinations. Novel receptor protein combinations permit recognition of novel antigens. Thus, adaptation in the immune system (i.e. the ability to respond to an unpredicted antigen) is a probabilistic outcome of this combinatorial strategy; that is, there is a certain probability that a novel receptor protein combination will be represented in the immune cell population that will be able to bind the novel antigen with high affinity.

However, receptor diversity in the olfactory system is not accomplished by developmentally regulated gene recombination

like in the immune system; rather, it has been accomplished by receptor repertoire expansion and diversification during evolution. The odorant receptor gene family is one of the largest gene families known and it is comprised of ~1000 genes in a typical mammal. The odorant receptor gene repertoire in mouse, for example, is over 1500 genes, which represents >5% of the entire coding content in the mouse genome. Humans and other primates have a smaller OR repertoire (see the following).

OR genes are organized in large clusters in the genome (Fig. 13a). In mouse, clusters range in size from one to more than 100 genes, although cluster sizes of approximately 30 ORs are more typical. Mouse OR clusters have been identified at >40 chromosomal locations and on all chromosomes but 12 and Y (Fig. 13b). Within clusters, the individual mouse OR genes are tightly spaced – a typical intergenic distance is ~20 kb. Accordingly, the OR gene structure is compact, consisting of a single coding exon, ~1 kb in size, and short 5′ and 3′ untranslated exons that are usually separated from the coding exon by 1 to 2 small introns. OR gene clusters are rarely, if ever, interrupted by non-OR genes, and in general, the regions of the genome housing OR clusters are gene-poor.

The functional significance of OR gene clustering, if any, is unknown. However, clustering is at least in part a product of frequent tandem gene duplication events that have taken place in evolution. Since the common ancestor of fish and mammals, OR repertoires have expanded by an order of magnitude (~100 genes in fish vs ~1000 genes in mammals). One wave of OR gene expansion occurred around the time when vertebrates were adapting to land (Fig. 13c). Approximately during the period when amphibians evolved ~370 MYA, a period of radiation occurred in which entire OR clusters duplicated to new locations in the genome. This expansion likely provided the basis for important adaptations in the olfactory system that permitted terrestrial vertebrates to recognize a repertoire of airborne chemicals with their noses.

Following this period of OR cluster radiation early in vertebrate evolution, the OR repertoire has evolved and expanded dynamically by local and nonlocal duplications of OR-containing gene blocks. These duplication events have occurred frequently and in some cases, very recently. For example, a subset of OR duplications near human telomeres have occurred so frequently that homologous blocks are dispersed on >10 chromosomes, and so recently that the copy number and locations of these OR blocks are polymorphic in the human population (Fig. 13a). Duplicated OR genes evolved new amino acid sequences, and thus presumably novel functions, by a number of evolutionary mechanisms. Duplicated ORs tend to be subject to frequent gene conversion events, and/or adaptive selection for amino acid change, all of which are mechanisms that tend to rapidly produce novel protein functions. Like the major histocompatibility (MHC) alleles, OR allelic variation in the human population appears to be unusually large, another indication that ORs have been recently adapting (Allelic variation refers to the numbers of different, or ''polymorphic,'' alleles represented in a population. Genes subject to adaptive selection tend to have high allelic variation.). The ongoing rapid evolution of OR gene repertoires in terrestrial vertebrates presumably reflects selective pressures to adapt to the specific olfactory requirements of individual species in their diverse and rapidly changing niches.

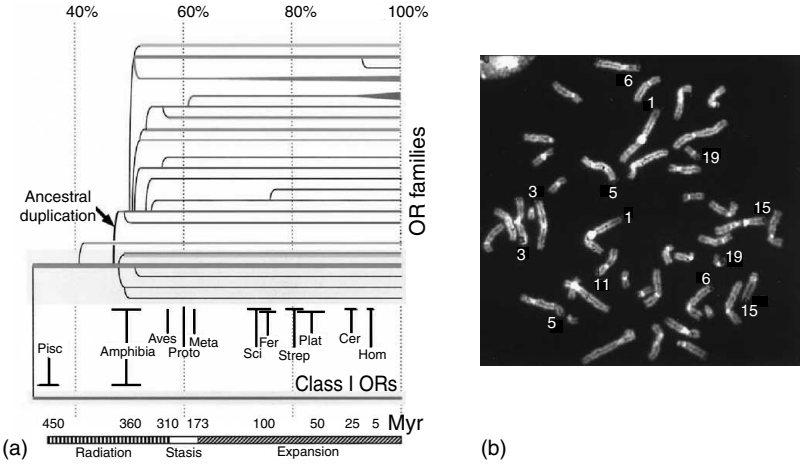

Fig. 13 OR evolution. (a) Application of a molecular clock based on subfamily sequence divergences (% divergence indicated above the tree) to infer periods of OR radiation and expansion during vertebrate evolution. According to this methodology, OR subfamily diversity arose predominantly during amphibian radiation, beginning ~370 million years ago (MYA). So-called "Class I" OR genes are described as *fish-like*, suggesting that these ORs are remnants of the preamphibian radiation. Taxonomy: Pisc = fish; Amphibia = frogs, salamander; Aves = chick; Proto = platypus; Meta = koala; Sci = marmot, mouse, rat; Fer: pig, dolphin, dog; Strep = lemurs, squirrel monkeys, Plat = marmoset; Cer = baboon, macaques; Hom = chimpanzee, gorilla. Figure modified from Glusman, G., Yanai, I., Rubin, I., Lancet, D. (2001) The complete human olfactory subgenome. *Genome Res.* **11**, 685–702. Copyright 2001 Cold Spring Harbor Laboratory Press. (b) Fluorescence *in situ* hybridization (FISH) on human chromosomes using a labeled probe (red) that recognizes a human subtelomeric OR sequence that is dispersed on seven human chromosomes (1, 3, 5, 6, 11, 15, 19) due to frequent duplication and translocation. The copy number and chromosomal distribution pattern of this OR locus is polymorphic in the human population, suggesting very recent duplications. Figure from Trask, B.J., Friedman, C., Martin-Gallardo, A., Rowen, L., Akinbami, C., Blankenship, J., Collins, C., Giorgi, D., Iadonato, S., Johnson, F., Kuo, W.-L., Massa, H., Morrish, T., Naylor, S., Nguyen, O.T.-H., Rouquier, S., Smith, T., Wong, D.J., Youngblom, J., van den Engh, G. (1998) Members of the olfactory receptor gene family are contained in large blocks of DNA duplicated polymorphically near the ends of human chromosomes. *Hum. Mol. Genet.* **7**, 13–26, by permission of Oxford University Press. (c) OR gene tree depicting evolutionary relationships between mouse (red) and human (blue) OR genes. Although the human OR repertoire is less than half the size of the mouse repertoire, the diversity of the human OR repertoire is comparable to that of the mouse repertoire. Therefore, it is expected that mice have better discriminatory power, but not necessarily a broader range of olfaction. Figure from Young et al., 2002 by permission of Oxford University Press. (d) Gene tree depicting species-specific expansion of a mouse and rat V1R subfamily. Most of the duplications occurred over a short period of evolution just after mouse and rat diverged. Fig. 13 (*Continued*)

The functional OR repertoire in many primates, including humans, is diminished. While the total number of human OR genes is estimated between 700 and 900 genes, more than half of these genes lack open reading frames that encode seven TM receptor proteins and, therefore, are probably pseudogenes. The rapid decline of the olfactory system in primates probably began shortly before the separation of hominoids and Old World monkeys, concurrent with the advent of trichromatic color vision. This development might have accelerated the displacement of the olfactory system with the visual system as the primary sensory modality in these animals. The evolution of upright posture could have also facilitated this olfactory decline, since such a development would distance the nose from the source of many important smells on the ground. However, humans still have >300 functional OR genes. The human OR repertoire is about as diverse as the mouse repertoire (Fig. 13c), suggesting that humans probably do not have reduced breadth or range of odor detection; rather, that humans may have reduced discriminatory power because of possessing fewer copies of similar genes. It is also important to note that since olfaction is considered a ''subliminal'' sense (the nose communicates with the subconscious limbic system), we humans may underestimate the influence of our olfactory systems on our own behavior. In later sections of this chapter, clinical implications of the olfactory system in human psychology/behavior are discussed.

6.2 Accessory Olfactory System

Like the main olfactory system, the sensory neurons in thevomeronasal organ (VNO) transduce signals via a G-protein-mediated pathway and predictably, the odorant receptors in the VNO, like the ORs in the main nose, are members of the seven TM/GPCR superfamily. There are two different populations of VNO sensory neurons, each of which express a different GPCR family. In mouse, the sensory neurons of the apical compartment of the VNO express the V1R receptor family, and the neurons of the basal compartment of the VNO express the V2R receptor family (Fig. 1). The ORs of the main nose, and the V1R and V2R genes of the VNO are all GPCRs. However, they are distinct gene families that do not share sequence homology, coupled to different G-proteins, and are expressed in mutually

exclusive populations of neurons. It is likely that the OR, V1R, and V2R receptor gene families represent an example of convergent evolution; that is, independent recruitment of chemosensory functions, as opposed to these three families sharing a common olfactory ancestry.

The V1Rs, like the ORs, have a simple gene structure of an intronless, ~1 kb coding sequence. Also, like the ORs, V1Rs are clustered in the genome. In mouse, there are over 300 V1R sequences (including 165 presumably functional intact genes) distributed on eight mouse chromosomes. In rat, there are over 200 V1R sequences (106 intact) distributed on six rat chromosomes. The large repertoire of intact V1Rs in these two rodent species, however, may be exceptional; recently, the canine V1R repertoire was estimated to consist of only eight intact V1R genes. The human and chimpanzee repertoires are estimated to be less than five intact V1R genes each, and, as noted earlier in this chapter, many primates, including humans, do not possess a functional VNO. Other mammalian species, such as pig, sheep, and ferret, also seem to have reduced VNO function as compared to rodents. Therefore, the rodent VNO might possess a greatly expanded range of specialized functions as compared to other mammals. Alternatively, the VNO in nonrodents might rely more heavily on contributions from the V2R gene family. To date, little is known about the repertoire sizes, genome organization, or biological functions of the mammalian V2R genes.

If V1R receptors are involved in mediating largely conspecific behaviors, as functional studies suggest, then species specificity in these receptors would be expected. A comparison of the mouse and rat V1R repertoires provides striking examples of species-specific expansions or contractions of specific V1R subfamilies (Fig. 13d). Moreover, the duplication events that gave rise to expanded subfamilies in the rodent genomes have been nonuniform, occurring predominantly over a short period of evolution that is coincident with the period when mouse and rat diverged. It is tempting to speculate that some of these species-specific expansions of particular V1R subfamilies helped reinforce mating/social barriers as these two rodent species diverged. However, the functions of individual V1R receptors and their ligands have not yet been elucidated, so the behavioral significance of these striking species-specific events in V1R evolution is unknown.

7 Basic Principles of Olfactory System Organization

How does the olfactory system coordinate the large repertoires of rapidly evolving receptor proteins in order to make sense of an odor? The basic organizing principle of the olfactory system was elucidated by two important discoveries: the discovery that each sensory neuron in the main olfactory epithelium expresses only ~1 OR gene, and that all neurons expressing any given OR gene extend their axons to a common target in the olfactory bulb. As discussed in the following sections, these two attributes of the olfactory system permit a combinatorial representation of smells in the brain – combinatorial patterns of neural activity that the brain can recognize and interpret as particular smells.

7.1 Monogenic Expression of Olfactory Receptor Genes

Several studies indicate that probably one OR gene is transcribed in each

olfactory sensory neuron. The evidence for this hypothesis was initially based on *in situ* hybridization studies conducted on rodent olfactory epithelium sections using individual OR gene probes. Each OR gene is expressed in one of four topological zones within the olfactory epithelium, and within a zone, each OR gene is transcribed in a ''punctate'' pattern (Fig. 14c). The fraction of cells transcribing RNA of any given OR gene is approximately one in a thousand. This expressing fraction (~0.1%) of olfactory sensory neurons is predicted by the one receptor-one neuron hypothesis, that is, if each olfactory sensory neuron expresses one of the ~1000 OR genes, and each OR is represented approximately equally in the population of olfactory sensory neurons, then any given OR gene should be expressed in ~1/1000 of the neurons. Yet, these studies are inconclusive due to numerous unknowns, such as, the frequency with which a particular OR probe cross-reacts with other similar OR sequences. Furthermore, some OR genes are expressed in more than 10 times the number of cells than other OR genes; therefore, not all OR probes are expected to exhibit a one-in-a-thousand expression pattern.

Another method to directly examine how many ORs are expressed in a single olfactory sensory neuron is to use single-cell reverse transcriptase polymerase chain reaction (RT-PCR) RT-PCR uses the reverse transcriptase enzyme to synthesize DNA templates complementary to RNA templates (cDNA). The cDNA templates can then be amplified by polymerase chain reaction (PCR) using degenerate OR primers to investigate the number of different ORs present in the template sample.

Degenerate PCR primers, designed against well-conserved amino acid sequences in the olfactory receptor protein are successful at amplifying ~50 to 70% of all OR templates in a single reaction. The complexity of OR degenerate PCR products can then be analyzed in bulk by restriction digestions, or by sequencing individual template products from the reaction. A few publications report the amplification of only one OR template in individual sensory neurons, consistent with the one receptor-one neuron hypothesis. However, the false negative rate with this technique is high – more than half of the cells tested do not produce detectable RT-PCR product of any OR cDNA – raising a question as to whether detecting a single OR product might also be an underestimation of the actual OR representation in that cell.

The most compelling evidence for mutually exclusive expression of OR genes is based on the fact that OR alleles are never, or rarely, coexpressed. This was first demonstrated for the two parental alleles of a single OR gene. In these experiments, allele-specific RT-PCR demonstrated that pools of olfactory sensory neuronal cells express one or the other allele, but not both. More recently, it was demonstrated that even identical OR transgenes are not coexpressed in the same neuron (Fig. 14d). (A transgene is a DNA segment typically constructed with a copy of an entire gene (including regulatory regions)). Thus, this principle of mutually exclusive OR expression is not limited to just endogenous alleles situated at homologous native positions on the two parental chromosomes; rather, it seems to apply to pairs of alleles situated anywhere in the genome. While monoallelic expression does not prove monogenic expression, the most parsimonious interpretation of these experiments is that, in general, only one OR locus is active per cell.

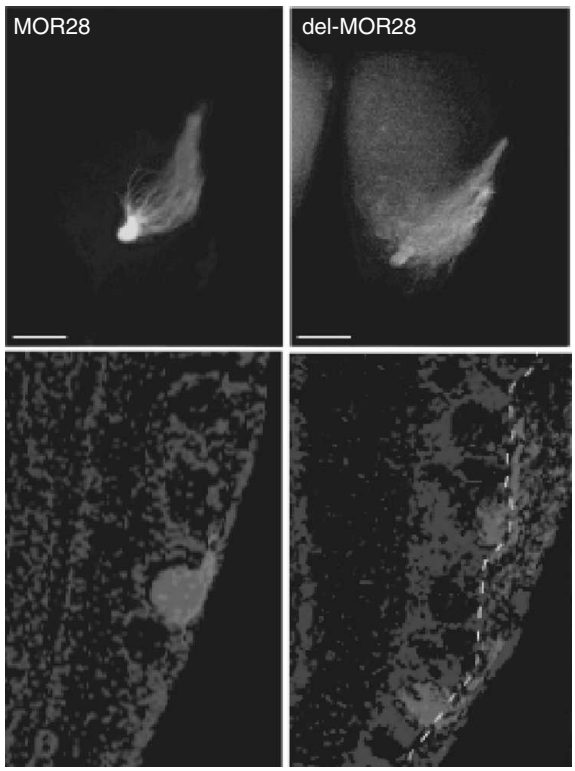
7.2

Convergence of Olfactory Receptor-expressing Neurons in the Olfactory Bulb

As discussed earlier, the expression pattern of any particular OR gene is ''punctate;'' that is, it is expressed in a seemingly random ~0.1% fraction of sensory neurons in the olfactory epithelium of the nose. Remarkably, despite originating from various positions throughout a given zone of the olfactory epithelium, each of the neurons that express a particular OR gene extend their axons to a common target in the olfactory bulb (Fig. 15a). The targets, where olfactory sensory neurons synapse with other central neurons, are called *glomeruli*. Since there are two bilaterally symmetrical olfactory bulbs per animal, the set of olfactory sensory neurons expressing a given OR gene projects axons to a pair of symmetric glomeruli per mouse.

Insights about the development of olfactory sensory neuronal projections to the olfactory bulb have come from *knockin* transgenic mouse lines in which specific endogenous ORs have been engineered to report all neurons expressing that OR in the animal. *Knockin* transgenic lines are lines in which an endogenous gene locus has been modified. OR *knockins* typically modify an endogenous OR locus so that it reports the expression of that locus. In 1998, this approach was used to show that the odorant receptor protein itself governs the convergence of like-expressing neurons to common glomeruli. When a marked OR locus has its coding sequence deleted, the neurons that report the activation of this locus fail to converge (Fig. 15a). Thus, by as yet undescribed mechanisms, an olfactory sensory neuron seems to select an olfactory receptor gene to express, and this choice governs the axon convergence of this neuron to a specific glomerulus dedicated to that particular OR.

In mice, there are ~2400 glomeruli (~1200 in each bulb), which will be formed with precise input from specific olfactory sensory neuronal populations. How does this topological map develop? How precise is the map? Does the map change with developmental time or with postnatal neural activity? Some important insights into the role of the OR protein itself in glomerulus targeting have come from ''receptor swapping'' experiments. Receptor ''swapping'' experiments replace the coding region of an OR locus with the coding region of another OR gene. These experiments test



(a)

Fig. 15 Convergence of olfactory sensory neurons expressing a particular OR protein. (a) As first demonstrated by Wang et al. (1998), axons that express a particular OR gene, such as MOR28, converge their axons onto a specific glomerulus target in the olfactory bulb. The left panel shows whole-mount (top) and coronal (bottom) views of multiple convergent GFP-tagged MOR28-expressing axons in the bulb. The right panel illustrates that this convergence is dependent on the expression of the OR gene itself. Whole-mount (top) and coronal (bottom) views of GFP-tagged neurons in which the MOR28 coding region is deleted do not converge. As discussed in Figure 6, these neurons select an alternative OR gene to express, and thus, these axons are likely converging onto other glomeruli specified by this alternative OR choice. Scale bars are 500 μm. Reprinted with permissions from Serizawa, S., Miyamichi, K., Nakatani, H., Suzuki, M., Saito, M., Yoshihara, Y., Sakano, H. (2003) Negative feedback regulation ensures the one receptor-one olfactory neuron rule in mouse. *Science* **302**, 2088–2094. Copyright 2003 AAAS. Permission from AAAS is required for all other uses. (b) Model depicting the central organizing principle of the olfactory system. Each olfactory sensory neuron in the olfactory epithelium expresses ~1 OR protein; a given OR gene expression is confined to one of four zones. All sensory neurons expressing a particular OR protein converge their axons onto a common glomerulus in the olfactory bulb. Thus, the stimulation of a subset of OR proteins from a particular smell causes neural activity at a specific combination of glomeruli, which is the neural signature of that smell. Figure from Mombaerts, P. (2001). How smell develops. *Nat. Neurosci Suppl.* **4**, 1192–1198. Reprinted with permission by Nature Publishing group.

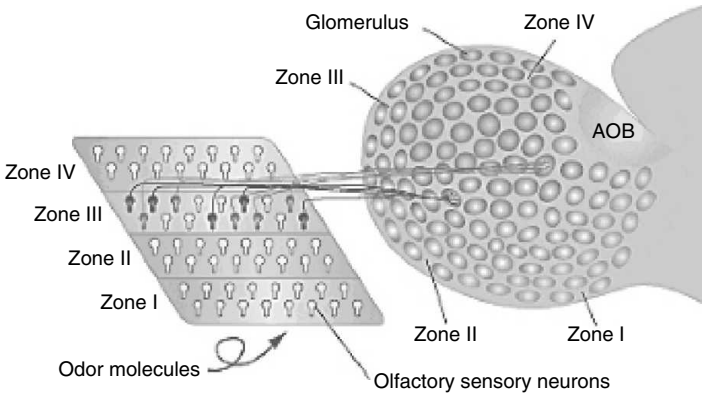


Fig. 15 (*Continued*)

whether the locus (i.e. the surrounding regulatory region) or the coding region of an OR gene are responsible for specifying the targeting of a sensory neuron to its correct glomerulus target. Replacement of the coding region of one OR gene with the coding region of another related OR gene expressed in the same epithelial zone causes neurons expressing the replaced OR to target glomeruli according to the donor OR. Thus, OR coding regions (and presumably the OR protein itself) is sufficient to direct glomerulus targeting. However, replacement of an OR coding region with an *OR* gene normally expressed in a different epithelial zone results in targeting to neither the donor nor the recipient glomerulus, rather, to an altogether unique glomerulus target. These data suggest that developmental context is important in the formation of the glomeruli map (i.e. OR influence on glomerulus targeting depends on the time/place of birth of the olfactory sensory neuron). Remarkably, even single amino acid substitutions in OR coding regions can result in novel glomerulus targeting. Moreover, a non-OR GPCR coding sequence (the $\beta 2$ adrenergic receptor) is able to substitute for an OR and form a glomerulus in the bulb. These data suggest that the sorting of olfactory sensory neurons in the bulb is exquisitely sensitive to OR sequence, yet able to accommodate almost any GPCR sequence.

Sensory neurons expressing a given OR start to become fasciculated as they enter the inner olfactory nerve layer, prior to entering the glomeruli neuropil. The path to a target glomerulus can be convoluted, yet determined, through a maze of other glomeruli. Many molecular guidance cues are likely to play a role in this remarkable projection. One promising candidate set of guidance cues are the *ephrin A* ligands and their *Eph* receptors. The *Eph* receptor tyrosine kinases have been implicated in the formation of the precise projection of retinal ganglion neurons in the visual system. In the visual system, the visual map is preserved between retina and target tissue (the optic tectum or superior colliculus) by a precise one-to-one spatial projection pattern in which retinal ganglion neurons maintain their relative positions. To accomplish this, a gradient of *EphA* receptors on the retinal axons and a gradient of two *ephrin* ligands in the target tissue specify nasotemporal

target positions in the visual map. The olfactory system may also use *EphA* receptors to specify geographic coordinates within the olfactory bulb. Olfactory sensory neurons express differing levels of two *ephrin A* ligands and target cells in the olfactory bulb express *Eph* receptors. Mutant mice lacking the two *ephrin A* ligands, or having increased *ephrin A* expression in subsets of neurons, mistarget their olfactory sensory neurons along the posterior–anterior axis. These data suggest that *ephrin A*s and their receptors are part of the code specifying target positions within the olfactory bulb.

The initial projection of olfactory sensory neurons to target glomeruli seems to be imperfect. For example, the sensory neurons expressing the *P*2 OR gene project axons to the glomerular layer at embryonic day 14.5–15.5; however, these early projections are not perfectly converged and mistargeting is observed; clean glomerulus targeting is not observed until well after the mouse is born. Studies with sensory neurons expressing a pair of similar ORs, *M71* and *M72*, suggest that glomerulus maturation requires sensory activity during a sensitive period specific for each glomerulus (i.e. this period is asynchronous for various OR-expressing populations) in order to achieve postnatal refinement of the map. Thus, maturation of the glomeruli map seems to be an activity-dependent process, as it is in the development of other sensory systems like the visual system.

8 The Combinatorial System of Odor Representation

With these two organizing principles – dedication of individual sensory neurons to the expression of a particular OR and the dedication of individual glomeruli to only sensory neurons expressing a given OR – the olfactory system is equipped to make sense of smells in the environment. The complex chemical quality of a smell is thus reduced to a precise combination of sensory neurons that are activated by that odorant blend, which in turn results in a precise combination of active glomeruli in the bulb (Fig. 15b). For example, if a mouse smells cheese, this means that the cheese is emitting a specific set of chemical compounds the mouse must recognize as a cheese smell. Some subset of OR proteins in the mouse nose will specifically recognize this set of compounds, leading to action potentials in the subset of neurons that express these ORs. Because like-neurons wire to like-glomeruli, these action potentials will be sent to a specific combination of glomeruli dedicated to this subset of OR-containing sensory neurons. The result is a pattern of glomeruli activity unique to the smell of cheese. This pattern of glomeruli activity would then be the digital representation of the smell of cheese to the mouse brain. Novel smells should produce novel combinations of activated glomeruli, a pattern of activity that could be learned/remembered by the animal if an association is made between the novel smell and its biological significance.

9 Transcriptional Regulation of Odor Receptor Genes

Thus far, we have described how OR genes have evolved in dynamic ways to modulate gene repertoires on timescales that permit individual species to adapt to their particular niches and lifestyles. Indeed, large OR repertoires, distributed widely in the

genome, seem to be continuously evolving by a robust gene birth/death process. This chapter also describes how the olfactory system is organized around the dedication of individual sensory neurons to individual OR proteins; that is, each individual olfactory sensory neuron transcribes only ~1 OR gene of the entire OR gene repertoire. With these two considerations, a bewildering enigma emerges: how does the transcriptional machinery in an olfactory sensory neuron transcribe only ~1 of ~1000 ORs, while keeping the remaining 99.9% of the OR genes silenced? Such a coregulatory system must operate genome-wide to accommodate the genome-wide distribution of OR genes, must be able to distinguish among OR genes that are tightly clustered and highly similar in sequence, and must be able to "keep track" of the full OR gene repertoire that is large in number and ever changing in evolution.

9.1 Singular Olfactory Receptor Gene Activation

In order for an olfactory sensory neuronal cell to execute one OR transcriptional event, it seems likely that there must be only one OR transcriptional assembly formed in that cell. At least four feasible mechanistic models fit this criterion (Fig. 16): (a) combinatorial promoters, (b) recombination into an active locus, (c) single activation complex, (d) and feedback inhibition.

In the *combinatorial promoters model* (Fig. 16a), each OR promoter could have a unique combination of transcription factor binding sites and each cell expresses a specific combination of these transcription factors. OR activation would then be due to some minimal combination of transcription factors assembled on one of the OR promoters, which will occur uniquely on the OR promoter that has binding sites for the specific combination of factors expressed in that cell. This model has been dismissed because of an experiment described previously (Fig. 16d). Identical transgenes, with identical cis regulatory sequences, are expressed in a mutually exclusive manner. Therefore, mutual exclusive transcription of OR genes is not due to unique transcription factor combinations assembled on a promoter. If it were, then the identical *cis* elements in these two transgenes would be expected to direct the expression of both transgenes in the same cell (since both transgenes would be expected to assemble exactly the same transcription factors on their identical promoter sequences).

In the *recombination into an active locus model* (Fig. 16b), each OR gene could have flanking signal sequences that permit the recombination ("cut and paste") or gene conversion ("copy and paste") of an OR locus into a single, mutually exclusive locus in the genome that is transcriptionally competent (i.e. in this model, native OR loci are transcriptionally incompetent; the OR transcription factor complex only forms at the promoter of the single active locus). Only one of the repertoire of OR genes in the genome can occupy the active locus in any given cell. This model has also been dismissed on several experimental grounds. First, RNA *in situ* hybridization studies on chromosomes from single cells demonstrate that OR RNA is produced from native loci and not from a common, nonnative locus in the genome. Second, two groups have successfully cloned a mouse from a single OR-expressing neuron, and in each case, the cloned mouse produces a

full complement of OR-expressing olfactory sensory neurons. This result argues that a cell's commitment to transcribe an OR gene is not irreversible, as would be predicted by changes in the actual DNA sequence.

In the *single activation complex model* (Fig. 16c), each OR promoter could compete for a single transcriptional complex that is assembled in one physical position in the nucleus. Only one of the repertoire of OR genes in the genome is able to stably associate with this complex in a given cell. Currently, there is no evidence to support or refute this model; however, it is a compelling model based on a process of elimination – it seems to be the best remaining model that would ensure exclusive OR activation. There is a biological precedent for this model. The ''trypanosome'' parasite mutually exclusively expresses a variable surface glycoprotein (VSG) – only one of a large repertoire of these VSG genes is expressed at a time. Monogenic expression is in part accomplished by an exclusive association of one VSG gene with a single transcriptional complex formed in the nucleus.

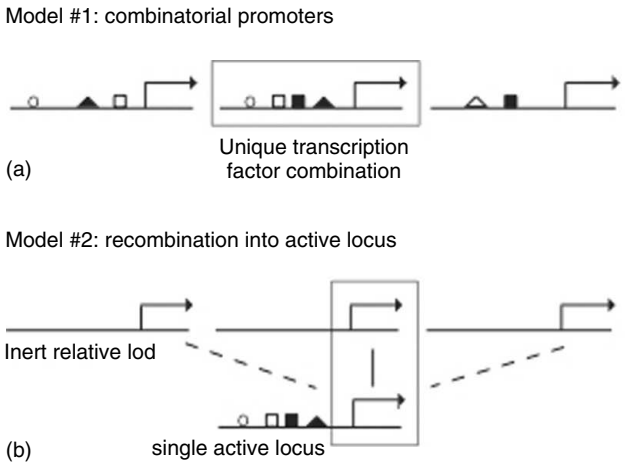

Fig. 16 Models to account for mutually exclusive OR expression. (a) In model #1, each OR promoter has a unique combination of cis elements and each olfactory sensory neuron expresses a combination of transcription factors. Only one OR promoter has this combination of binding sites and is thus, uniquely active in that cell. In the example shown, the binding of four factors is sufficient to activate the middle gene. (b) In model #2, inert OR loci compete to recombine their coding regions into a single active locus in the genome. This model is conceptually similar to the yeast mating type locus. (c) In model #3, each OR promoter competes to associate with a unique transcription factor complex in the nucleus. This model is conceptually similar to the ''pol body'' utilized by trypanosomes to express only one variable surface glycoprotein (reference). (d) In model #4, transcriptional activation is inefficient such that ~1 OR reaches a superthreshold level of activation first, and this winning gene then inhibits all other loci, thereby securing its unique expression status in the cell. Reprinted with permission from Elsevier.

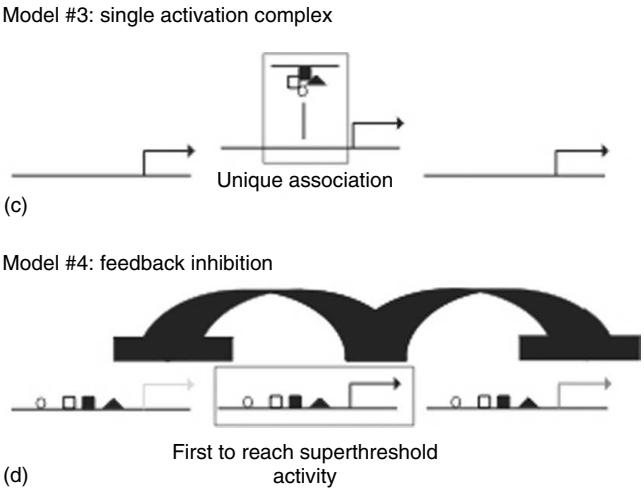

Fig. 16 (*Continued*)

In the *feedback inhibition model* (Fig. 16d), each OR gene could be competent to be transcribed; however, only ~1 OR gene manages to establish an above-threshold activation state. Once this above-threshold activation state is established, this ''winning'' OR gene is able to negatively feed back onto all other loci, thus closing their opportunity to reach this same level of activation. This model has recently gained momentum on the basis of two independent studies that demonstrate that OR gene selection can take place more than once during a cell's maturation. Specifically, an OR locus can be initially selected; however, if the protein product of this OR gene fails to be produced, the neuron will select another OR locus (Fig. 14e). This alternative OR choice does not appear to be constrained to one or a small number of alternative options: the population of labeled neurons that initially selected the transgene locus is now able to select among a diverse set of secondary OR options and accordingly, project axons to a diverse set of target glomeruli (Fig. 15a).

Notably, the presence of OR protein, as opposed to just RNA, is required to stabilize the OR choice, because expression of transgenes with frameshift mutations (not capable of translating a functional OR protein but still capable of transcription of the RNA) leads to the cell making an alternative choice. Such a mechanism may be the reason why so many OR pseudogenes are tolerated in the genome – if a pseudogene is haphazardly expressed (because of a still active promoter), the absence of a functional protein would, by this feedback mechanism, eventually lead to a functional selection. The molecular details of this feedback pathway are still unknown; however, there is a biological precedent in the immune system that could provide hints. In B cells of the immune system, the pre-B receptor, once stably expressed, signals via a tyrosine kinase pathway to prohibit further activation of B-cell receptor loci.

The feedback inhibition model (Fig. 16d) and the single activation complex (Fig. 16c) are not mutually exclusive models. It is possible that singular activation is accomplished initially by an exclusive association

with a unique transcription factor complex (Fig. 16c), but stabile commitment to this choice requires feedback that the selected OR locus is producing a functional OR protein. Alternatively, singular OR activation prior to feedback inhibition could be a probabilistic outcome of OR transcriptional activation being a rare or inefficient process. In such a scenario, exclusive OR activation would not necessarily be absolute – the ''winning'' OR gene has presumably reached a superthreshold state of activation first, but there is not an inherent physical barrier in the model to prevent more than one OR gene reaching this same threshold of activation. The probability of reaching a state of activation must be low so that, on average, only one of a thousand genes reaches this status first. This presumed inefficiency is likely to be at the transcriptional level, since by RT-PCR and other molecular methods, more than one abundant OR mRNA in a cell is generally not observed. Weak promoters, limited enhancement, and/or repressive chromatin could contribute to protracted kinetics of OR activation.

9.2 Olfactory Receptor Regulatory Elements

The expression patterns of olfactory receptor genes (Fig. 9) indicate several regulatory features presumably governed by transcription factors interacting with local regulatory elements. First, the olfactory receptor must be activated in the correct cell type and at the correct developmental time. While there are reports of expression of OR genes in nonolfactory tissue, most notably male germ cells in which some OR proteins have been proposed to play a role in chemoreception during sperm–egg communication, all OR gene promoters are presumably interacting with transcription factors expressed in mature olfactory sensory neurons. Second, subsets of olfactory receptor genes are activated within particular topological zones in the olfactory epithelium. Four major geographical zones along the dorsal–ventral axis have been described (Fig. 14); most OR genes examined are expressed widely within only one of these four zones. Some OR genes, however, do not conform to this stereotypic pattern of expression; for example, some ORs are reported to have restricted expression medially between the two dorsalmost zones. Third, as discussed previously, each OR gene must contain regulatory elements that govern mutually exclusive expression. Such elements could bind factors contained with a singular activation complex (see Fig. 16c) or repressors that could be part of a feedback inhibition pathway (see Fig. 16d).

Inspection of mouse genomic sequences have not revealed any universal motifs shared among OR gene promoters, even among subsets of OR genes known to be expressed in the same topological zones. Transgenic approaches have been most fruitful at identifying important *cis* elements. Such experiments aim to elucidate the minimum genomic fragment that, when placed upstream of an OR transgene, can report an expression pattern that recapitulates the *in vivo* expression pattern of the endogenous OR gene. Since stable activation of a single OR gene requires the presence of the OR protein itself (Fig. 14e), OR transgenes are typically designed to produce a bi-cistronic mRNA: both a reporter protein (e.g. *β-galactosidase*) and the OR protein are produced from a single transcript. This is accomplished by inserting an internal ribosomal entry site (IRES) upstream of the second reporter coding region in the transgene construct, so that the ribosome will initiate translation both

at the 5′ end of the transcript as usual (to translate the OR protein), as well as at an internal site just upstream of the reporter coding region (see Fig. 17A). These transgenes are integrated randomly into the mouse genome to produce a transgenic mouse, which can be bred to homozygosity.

Recently, researchers at Rockefeller University produced a minimal OR "minigene" (<10 kb) that recapitulated the expression pattern of the endogenous copy of this OR (Fig. 17A). Approximately 400 bp upstream of the transcription start site was necessary to visualize any expression of the transgene reporter. Given how little upstream sequence is required for transgene expression, the *cis* regulatory region of a typical OR gene seems to be quite proximal. Several additional transgene experiments (with one exception, discussed in the following sections) support the hypothesis that OR regulation is governed locally, presumably within the genomic space between ORs in a cluster. Removal of the 5′ introns of the minigene construct resulted in additional expression outside the normal zonal boundary, implying that zonal restriction is due to inhibitory mechanisms. Sequences 3′ to the coding region do not seem to be important for the transcriptional regulation of this minigene, as well as a panel of other transgenes so far examined. With the putative regulatory territory narrowing, several researchers are now scrutinizing these sequences and using various methods to begin to identify transcription factors that interact with these OR regulatory regions. Other researchers have identified transcription factors that interact with conserved sequences proximal to transcription start sites of a set of closely related OR genes. These experiments yielded six putative OR regulators, including the O/E-2(OS) helix–loop–helix transcription factor, already thought to drive expression of other olfactory neuronal-specific genes, and several homeobox factors that are involved in pattern formation in other tissues.

The paradigm that OR genes are autonomously regulated by proximal elements is supported by several examples of successful mini-transgenes. However, there is one compelling counterexample that indicates some ORs may be coregulated by distant locus control regions (LCRs). In 2000, the Sakano group began characterizing the regulatory structures of a cluster of OR genes that are adjacent to the V-α gene segments of the T-cell receptor (TCR) locus on mouse chromosome 14. In this case, only large ~200-kb OR transgene constructs were successfully expressed. The group later identified a distant ~2-kb sequence, termed the *H region*, required for activation of OR genes in the cluster (Fig. 17B). This enhancer is situated ~75 kb away from the OR cluster and between the OR and TCR gene clusters. Thus, at least this one OR locus seems to be regulated by an LCR, reminiscent of the LCR-mediated coregulation of clustered globin genes. H-region homology has not been identified at other OR loci, suggesting it may be a special feature of this particular OR locus. It is possible that this cluster of OR genes has weak local promoters that require additional enhancement in order to be able to compete with other OR loci for activation. One of the functions postulated for the globin LCR is to open the chromatin structure within the globin locus so that transcription factors are able to access individual globin gene promoters. Similarly, it is possible that extra enhancement from the H region might be needed at this OR locus to counterbalance repressive position effects from the adjacent T-cell

receptor locus, which is transcriptionally silenced in olfactory neurons.

In summary, ~1 OR gene is expressed per mature sensory neuron, and this mutually exclusive expression permits individual neurons to be dedicated to respond to specific odorants. An activated OR locus that produces an intact OR protein is able to inhibit the activation of other OR loci. Each OR gene is expressed in a seemingly random set of sensory neurons, generally within one of four spatial zones in the olfactory epithelium. The sequences responsible for governing OR expression in the correct zone and in a mutually exclusive way appear to be proximal and autonomous, and thus, OR genes do not generally appear to be dependent on their native locus or on clustered relationships for correct expression. The one well-characterized counterexample, the locus-dependent coregulation of an OR gene cluster near the T-cell receptor locus, hints that some OR clusters require additional enhancement, possibly because of having weak local promoters or because

In each case, the OR coding region (yellow) is constructed with a downstream internal ribosome entry sequence (i) and reporter gene (*tauLac*Z). The wild-type construct (top) contains 400 bp upstream of the transcription start site, the two 5′ untranslated exons (orange) and introns, and >1 kb 3′ noncoding region. This construct reports the wild-type expression pattern of the mOR23 gene in olfactory sensory neurons. The table reports expression patterns for various deleted constructs; that is, whether the deleted transgene is expressed at detectable levels in olfactory sensory neurons (OSNs), whether its expression is within epithelial zone 4 (the normal zone of expression for mOR23), whether it expresses ectopically outside zone 4 (Ecto. zone), whether the mOR23 transgene exhibits mutually exclusive (Mut. excl.) expression with the endogenous mOR23 gene, whether the OSNs expressing the construct exhibit convergence onto the endogenous mOR23 glomerulus in the olfactory bulb (Co-conv.), and/or whether the OSNs expressing the construct extend axons to multiple glomeruli (+glom.). Deletion of the 400 bp just upstream of the transcription start site of mOR23 abolishes expression of the transgene (bottom construct, a). Deletion of 5′ introns results in transgene expression outside zone 4 (b). Deletion of sequences 3′ to the coding region do not seem to have an effect. Figure modified from Neuron, Vol. 4, Vassalli, A., Rothman, A., Feinstein, P., Zapotocky, M., Mombaerts, P. (2002) Minigenes impart odorant receptor-specific axon guidance in the olfactory bulb, pages 681–696. Copyright 2002, with permission from Elsevier. (B) Expression of OR genes from the MOR28 locus on mouse chromosome 14 requires a distant enhancer, the "H region." Various truncated constructs in which the H region is missing do not report MOR28 expression. The H region is situated ~75 kb upstream of the *MOR28* gene and between the MOR28 OR locus and the T-cell receptor (TCR) Vα gene segments. Inset, dot matrix plot showing conservation of the H region between mouse and human (diagonal trace within box). (2003) Negative feedback regulation ensures the one receptor-one olfactory neuron rule in mouse. *Science* **302**, 2088–2094. Copyright 2003 AAAS. (See color plate p. l.)

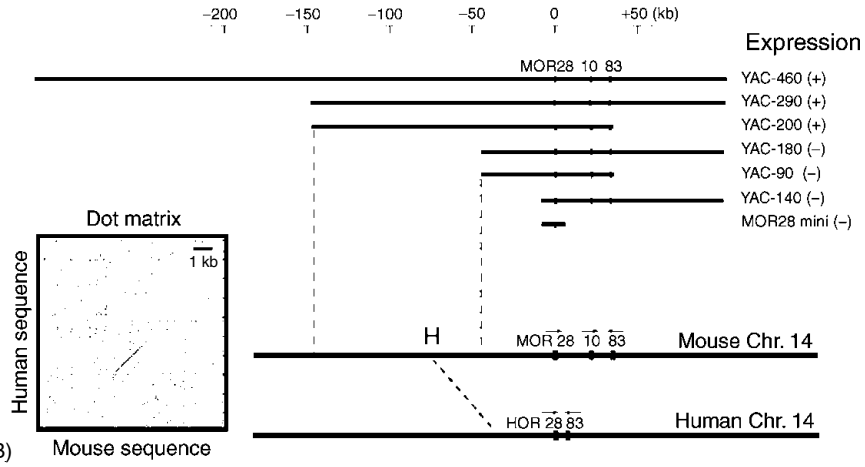

Fig. 17 (*Continued*)

of positioning in an especially repressed region of the genome. The problem of how a large and rapidly evolving repertoire of olfactory receptor genes is so exquisitely regulated remains one of the more intriguing puzzles in molecular biology.

10
Human Diseases Associated with Genetic Defects and Smell Dysfunction

Despite the aforementioned advances in understanding factors associated with signal transduction and the chemotopographic anatomy of the olfactory pathways, such knowledge has shed little light on cases of smell loss and distortion that plague the human population. Most cases of olfactory dysfunction are acquired in adulthood, reflecting damage to the olfactory neuroepithelium secondary to insults from various infections (e.g. viral, bacterial), head trauma, and exposure to xenobiotic agents (e.g. pollutants, industrial dusts, metals, and volatiles). Nevertheless, the advances being made in understanding the processes of olfactory receptor cell regeneration will undoubtedly, in the not-too-distant future, have clinical applications.

That being said, there are numerous inherited diseases associated with olfactory dysfunction. Some of these disorders relate to the abnormal development of the olfactory bulbs and tracts and have an anosmic phenotype. In other cases, the olfactory losses are subtle and of unknown physiologic origin. Alterations in olfaction are only now being discovered in a number of diseases, largely as a result of the development of easy-to-use commercially available quantitative tests of olfactory function. Listed in the following sections are major diseases with at least some heritable component for which quantitative olfactory testing has documented the dysfunction. This listing is representative, and not inclusive.

10.1
Congenital Disorders Associated with Olfactory Dysfunction

There are numerous congenital diseases for which olfactory dysfunction, usually

anosmia, is a key marker. In most cases, a genetic linkage is clear, although in others it is only indirectly inferred and difficult to differentiate from neurodevelopmental problems of unknown cause that can intervene during fetal development.

10.1.1 Bardet–Biedl Syndrome

Bardet–Biedl syndrome (BBS), also known as the *Laurence–Moon–Bardet–Biedl syndrome*, is caused by mutations in at least eight loci, seven of which are now identified. Three of these loci (BBS4, BBS5, and BBS8) encode gene products that are localized to the basal body of cultured cells at ciliated tissue borders. Half of BBS are anosmic or markedly hyposmic. Interestingly, in the study defining the olfactory loss in this syndrome, 4 of 6 patients with mutations in BBS1 (the most common BBS-associated mutation), and 3 of 3 patients with mutations in BBS8, had normal olfactory function, implying multiple gene involvement in the olfactory loss. Mice with the BBS4 gene knocked out have less Type III adenylyl cyclase and $G\gamma_{13}$ signal transduction components in their atypically short cilia. The cilia within the respiratory epithelium are normal. Such mice are anosmic or hyposmic, as measured by reduced EOG amplitudes to a wide range of odorants.

10.1.2 Down Syndrome

Down syndrome (DS) is the most common form of human mental retardation. This trisomy 21 disorder accounts for ~17% of the mentally challenged population. Persons with DS have difficulty in smelling. Given that the average smell loss observed in DS is very close to that observed in Alzheimer's disease (AD), and those individuals with DS who live into early adulthood inevitably develop the clinical and neuropathological features of AD, the question arises as to whether DS and AD share a common olfactory neuropathology. While this is possible, there are several lines of evidence that suggest this may not be the case. First, IQ matched non-DS retarded persons exhibit the same degree of smell dysfunction as seen in DS. Second, the smell loss in DS occurs earlier than that of the neuropathology, at least in terms of senile plaques and diffuse amyloid deposits. The latter generally begin to occur around the age of 19, with significant numbers occurring in the 20s. However, juveniles with DS as young as the age of 11 exhibit the same level of olfactory dysfunction as older DS individuals. Hence, the cause of the olfactory loss remains obscure.

10.1.3 Friedreich Ataxia

Friedreich ataxia is the most common inherited form of ataxia (diseases associated with extreme loss of muscle and movement coordination). This disorder is caused by an abnormal expansion of a GAA trinucleotide repeat sequence in intron 1 of the *FRDA* gene. This sequence is genetically unstable and polymorphic. At the FRDA locus, disease-causing expanded (E) alleles, containing 66–1700 triplets, interfere with gene transcription, resulting in frataxin deficiency and Friedreich's ataxia. The cause of the relatively mild loss of olfactory function in this disorder is unknown, although it is of interest that there is evidence that the cerebellum, per se, may play a role in higher-order olfactory processing. Support for this concept includes (1) early reports of olfactory deficits in patients with tumors in or near the cerebellum; (2) evidence that the staggered mutant mouse, a mouse with functional deficits

in the olivocerebellar pathway, is hyposmic; and (3) functional imaging studies of normal subjects demonstrating marked odor-induced hypermetabolic activity independent of sniffing within regions of the cerebellum. Despite such findings, the actual cause of the olfactory disturbance is not understood.

10.1.4 Kallmann Syndrome

Perhaps the best-known congenital anosmic condition is Kallmann syndrome (KS). In KS, the olfactory bulbs and tracts fail to develop or exhibit significant malformation. Additionally, this disorder is characterized by hypogonadotropic hypogonadism, often first noted as the failure to achieve puberty. Deficits in a gene (*FGFR1*) involved in olfactory development and neuron chimiotactism are believed to be the basis for the malformation of the bulbs and tracts in this disorder. The hypogonadism of this KS appears to reflect mutations of the gonadotrophin releasing factor (GnRH) receptor via the *GPR54* gene.

10.1.5 Pseudohypoparathyroidism and Pseudopseudohypoparathyroidism

Prior to the discovery of G_{olf}, support for the hypothesis that another G-protein, $G_{s\alpha}$, plays a major role in the initial phases of olfactory transduction in humans came from findings of variably decreased olfactory ability in Type Ia pseudohypoparathyroidism (PHP). PHP is a syndrome in which generalized hormone resistance is associated with a deficiency of $G_{s\alpha}$, as measured in red blood cells. However, these patients have other problems that might cause or contribute to their olfactory dysfunction, including an unusual constellation of skeletal and developmental deficits termed *Albright hereditary osteodystrophy* (AHO). More recent research, while confirming that PHP Type Ia patients have defective olfaction, also found that patients with Type Ib PHP, who have no AHO, no generalized hormone resistance, and normal $G_{s\alpha}$ activity exhibit olfactory dysfunction relative to matched controls. Furthermore, this work found that patients with pseudopseudohypoparathyroidism (PPHP), who have AHO, no generalized hormone resistance, and deficient $G_{s\alpha}$ protein activity, have relatively normal olfactory function. These observations do not support the hypothesis that the olfactory dysfunction associated with PHP is the result of generalized $G_{s\alpha}$ protein deficiency, and imply that other mechanisms are responsible for the olfactory deficits of this disorder. Whether G_{olf} is deficient in the olfactory epithelia of PHP patients has not been determined.

10.2 Neurodegenerative Diseases

Some clearly inherited neurodegenerative diseases in addition to DS are associated with smell dysfunction, the classic example being Huntington disease. The genetic involvement in a number of other neurodegenerative disorders, such as multiple sclerosis and most forms of Alzheimer's disease and idiopathic Parkinson's disease, is less clear. Moreover, the causes of the olfactory losses in nearly all neurodegenerative diseases are poorly understood, and only recently have some forms of such diseases been linked to specific genes. In many cases, the olfactory phenotype appears prior to the onset of other symptoms of the disorder. Inferences based upon twin studies, the fact that relatives are more susceptible to the disease, and associations with risk factors such as the *APOE-4* gene

imply heritable elements, although interactions with environmental factors cannot be ruled out.

10.2.1 Alzheimer's Disease

AD, the most common form of dementia, is an idiopathic slowly developing degenerative disease most notable for its memory loss. Smell dysfunction is present in a large proportion of AD patients (85–90%) bilaterally early in the disease process, apparently preceding classic cognitive elements of the disorder. Some inherited forms of AD exhibit smell loss, and the loss observed in idiopathic AD correlates with a family history of dementia, implying genetic linkage. Importantly, there is an association between the AD-related olfactory dysfunction and presence of the APOE-4 allele. For example, in 1999 one group of investigators administered a standardized 12-item smell identification test to 1604 nondemented community-dwelling senior citizens 65 years of age or older. Over a subsequent 2-year time period, the scores on this test were found to be a better predictor of cognitive decline than scores on a global cognitive test. Persons who were anosmic and possessed at least one APOE-4 allele had 4.9 times the risk of having cognitive decline than normosmic persons not possessing this allele. This contrasts with the 1.23 times greater risk for cognitive decline in normosmic individuals possessing at least one such APOE allele. When the data were stratified by sex, women who were anosmic and possessed at least one APOE-4 allele had an odds ratio of 9.71, compared to an odds ratio of 1.90 for women who were normosmic and possessed at least one allele. The corresponding odds ratios for men were 3.18 and 0.67, respectively.

10.2.2 Huntington's Disease

Huntington's disease (HD) is an inherited autosomal dominant neurodegenerative disorder whose phenotype typically manifests between the ages of 30 and 40, although onset can occur at any age. Studies evaluating olfactory function in HD patients have found no dysfunction in gene carriers before the time of the expression of the classical phenotypes of the disease, although it is not yet known whether the smell loss precedes such expression by a year or two, as is seen in AD and Parkinson's disease (PD). The locus for HD is located on the short (p) arm of chromosome 4 at position 16.3. Patients with this disease have from 40 to over 100 trinucleotide repeats (cytosine-adenine-guanine), which is considerably higher than the repeat number normally present (less than 30). There is a rough inverse correlation between the abnormal number of CAG repeats and the age of onset of phenotypic expression, although this is not a clinically useful predictor of either the age of symptom onset or the rate of progression in individual patients.

10.2.3 Multiple Sclerosis

Approximately a quarter of MS patients will exhibit, at any one time, some degree of olfactory dysfunction and, in rare instances such dysfunction can be the presenting symptom of MS. The olfactory loss is intimately related to the plaque-related activity in the subtemporal and subfrontal regions of the brain, such that an inverse relation exists between the number of such plaques and scores on an odor identification test. Such an association is not present with plaque numbers or volumes outside of these olfaction-related brain regions. Longitudinal assessment of smell function in individual MS patients demonstrates a waxing and waning of their olfactory

test scores that occurs in concert with the exacerbation and remission of plaque activity within the subtemporal and subfrontal brain regions. Thus, the olfactory dysfunction is directly associated with the poorly understood cycle of inflammatory processes associated with the disease proper.

10.2.4 Parkinson's Disease

In recent years, it has become apparent that idiopathic PD is not solely a disease of motor dysfunction, but is accompanied by subtle alterations in vision and hearing, and not-so-subtle alterations in the ability to smell. Indeed, like AD, bilateral smell loss is a major component of this disease, with its prevalence being from 85 to 90% of all tested cases – a prevalence greater than that of tremor and rigidity, two of PD's cardinal diagnostic signs. It is noteworthy that James Parkinson, for whom this disorder is named, indicated in his classic description of this disorder that no sensory anomalies were present. It has been speculated that had the smell dysfunction of PD been a visual dysfunction, Parkinson may well have been forced to classify the disorder primarily as a visual one with secondary motor deficits.

The olfactory deficit of PD is not caused by a deficiency in dopamine, as treatment with dihydroxyphenylalanine (L-DOPA) and dopamine agonists have no influence on the dysfunction, which occurs as severely in nonmedicated or never-medicated patients as in medicated ones. As in AD, total anosmia is not the rule for PD, despite its severity and high prevalence. Thus, in one study only 13% of 38 patients who received an odor detection threshold test were unable to detect the highest odorant concentration presented, and only 38.3% of 81 patients had odor identification scores suggestive of anosmia. Moreover, all but one of 41 patients who were asked if an odor was present on each of 40 odorant items answered affirmatively to 35 or more of the items, even though the majority were unable to identify most of the odors, or felt that the perceived sensation did not correspond to the response alternatives. Nonetheless, olfactory testing can easily discriminate between persons with and without PD, including persons with other forms of parkinsonism. The sensitivity and specificity of the 40-item smell test in differentiating between clinically diagnosed PD patients and normal controls was reported in one study as 91 and 80%, respectively, in males $\leq$ 60 years of age. Another study reported the overall sensitivity and specificity of such testing in distinguishing between older persons with PD (mean = 72.6 yrs) and vascular parkinsonism (mean = 74.1 yrs) to be 85.7 and 88.9%, respectively. When the latter data were divided into two categories on the basis of the patient's age (65–75 and 76–88 yrs), the sensitivity and specificity values were 100 and 85.7%, and 85.7 and 80%, respectively. Olfactory testing has been shown to clearly differentiate idiopathic PD from a number of other neurodegenerative diseases with motor symptoms, including disorders often misdiagnosed as PD such as progressive supranuclear palsy (PSP), MPTP-induced PD, and essential tremor.

The genetic contribution to the olfactory loss seen in PD is not clear. However, a recent study found patients with early onset autosomal recessive juvenile parkinsonism associated with the *PARK2* mutation (termed *parkin disease*) have odor identification test scores that do not differ from normal controls. In contrast, individuals with early onset parkinsonism not associated with this mutation exhibit olfactory dysfunction similar to that of adult-onset PD, suggesting that parkin disease may

be a quite different entity than early onset parkinsonism.

11 Summary

The sense of smell is critically important for a broad range of organisms, including our own species. In this chapter, we have described an array of processes involved in peripheral elements of olfactory transduction and how evolution has shaped the receptor repertoire of mammals. Although there is yet much to learn, it is apparent that major advances have been made during the last few decades in our understanding of the mammalian olfactory system and that this field is one of the most active fields of neuroscience. It is also apparent that the complexity of this exquisite sensory system rivals that of any other sensory system.

Among the major advances of the last 20 years are (1) the identification of gene families that express olfactory receptors, (2) the elucidation of membrane mechanisms responsible for stimulus transduction and second messenger signaling, (3) mapping of the topography of receptor-specific pathways through the system, (4) establishing the nature and location of synaptic microcircuits within the olfactory bulb and higher olfaction-related brain regions, and (5) understanding and articulating the general plasticity of the olfactory system, including cell replacement within the olfactory neuroepithelium and olfactory bulb. Such advances, along with those in establishing the causes of smell dysfunction in a variety of genetically determined clinical disorders, make it clear that the next few decades will be exciting ones for further understanding of the sense of smell.

Keywords

Expressed Sequence Tag (EST)
A partial, usually 200–800 nucleotides long fragment of cDNA, obtained by single-pass sequencing of a randomly selected clone isolated from a cell or tissue cDNA library.

Microarray
A glass slide that contains hundreds to several thousands ordered cDNA probes to measure gene expression levels by hybridization analysis of labeled cDNAs.

Polymerase Chain Reaction
Referred to as PCR, it consists of an *in vitro* enzymatic amplification of specific DNA sequences.

Single Nucleotide Polymorphism
A DNA sequence variation that occurs when a single nucleotide in the genome sequence is changed to another one.

Transcriptome
The molecular phenotype of a cell, as defined by the diversity and abundance of mRNAs, differs between normal, developmental, and disease conditions.

Type IIS Restriction Endonuclease
A restriction enzyme that cleaves at a defined distance away from its asymmetric recognition site.

Serial Analysis of Gene Expression (SAGE) is a method designed to measure the abundance of a large number of mRNAs in tissues and cells to characterize their transcriptome. By the end of the twentieth century, when determining the entire genomic sequence of higher organisms began to be perceived as a realistic and attainable goal, the interest for genome-wide analysis of gene expression rapidly increased. One of the first strategies was to generate expressed sequence tags (ESTs), that is, partial sequences of cDNA clones randomly selected in libraries prepared from various tissue samples. The EST approach was highly valuable for gene discovery. Moreover, as long as the abundance of a given mRNA could be correlated with the frequency of its EST, it might also provide quantitative information. However, this approach evaluated only a limited number of genes per library. Obviously, getting larger quantitative expression profiles required to increase the rate of acquisition of experimental data. SAGE rests on the sequencing of short diagnostic tags, and as such increased by more than 1 order of magnitude the number of transcripts analyzed by current sequencing methods. Sets of 100 000 SAGE tags are now routinely sequenced, making possible the quantification of low copy number mRNAs.

1 Methodology

1.1 Rationale for SAGE

A major principle of serial analysis of gene expression (SAGE) was to reduce expressed sequence tags (ESTs) to their minimal size by using a type IIS restriction enzyme (Fig. 1). Type IIS endonucleases cleave DNA at a defined distance from their asymmetric recognition site. *Bsm* FI was chosen to generate the conventional SAGE 14-bp tags from a defined (anchoring) site created by a conventional restriction enzyme near the 3′ end of each cDNA. Following the four common nucleotides of this anchoring site, SAGE tags differ by the next 10 variable nucleotides. Associated with the positional information, this size is usually sufficient for identifying each transcript, considering that 1 048 576 (4^{10}) different sequences can be distinguished. However, it may not be sufficient to map tags directly onto the complex genome of higher vertebrates: another endonuclease, *Mme* I, generating 21-bp tags, was preferred when using SAGE to annotate the genome by the so-called LongSAGE method.

One of the most appealing features of SAGE was the strategy used to amplify the whole population of tags while preserving the same quantitative distribution as in the initial mRNA population. Another characteristic of SAGE was to assemble tags into concatemers before DNA sequence analysis so that multiple tags (20–30 or more) could be read from each sequencing lane. Specific computer tools were developed for extracting the list of tags from sequence files, counting the number of times each one is observed and identifying the corresponding genes.

A SAGE analysis eventually results in a large sequence file in which tag sequences are punctuated by the four nucleotides of each anchoring site. Because experimental datasets are obtained *de novo* and do not rely on the calibration of any physical instrument, revocable external data or historical context, SAGE data can be considered as definitively acquired. Absolute transcript numbers are directly provided in a digital format, and data from multiple laboratories are easily assembled in comprehensive databases (Table 1). Tag-to-gene assignment can be updated at any time to keep in pace with progress in genome annotation, and an increasing body of functional annotations can be registered in the database. SAGE has now become one of the leading methods for gene expression profiling.

1.2 How SAGE Libraries are Built: The Original Method and Further Improvements

Poly(A) RNAs are preferably isolated using oligo$(dT)_{25}$ covalently linked to paramagnetic beads (Fig. 1). Other methods such as oligo(dT)-cellulose chromatography provide highly variable yields of mRNAs contaminated by substantial amounts of ribosomal RNAs (see Sect. 1.5). Thus, it is not surprising that the very first SAGE protocol, described in 1995, required 5 µg poly(A) RNA (i.e. several millions of mammalian cells). The need to work on small biological samples prompted several investigators to adapt the method to downsized extracts as in the SADE, microSAGE, and miniSAGE protocols. It then became possible to build SAGE libraries starting from 1 µg total RNA and to analyze biological samples containing 10^5 cells or even less. It is still possible to lower sample size and to start from 2500 cells or as little as

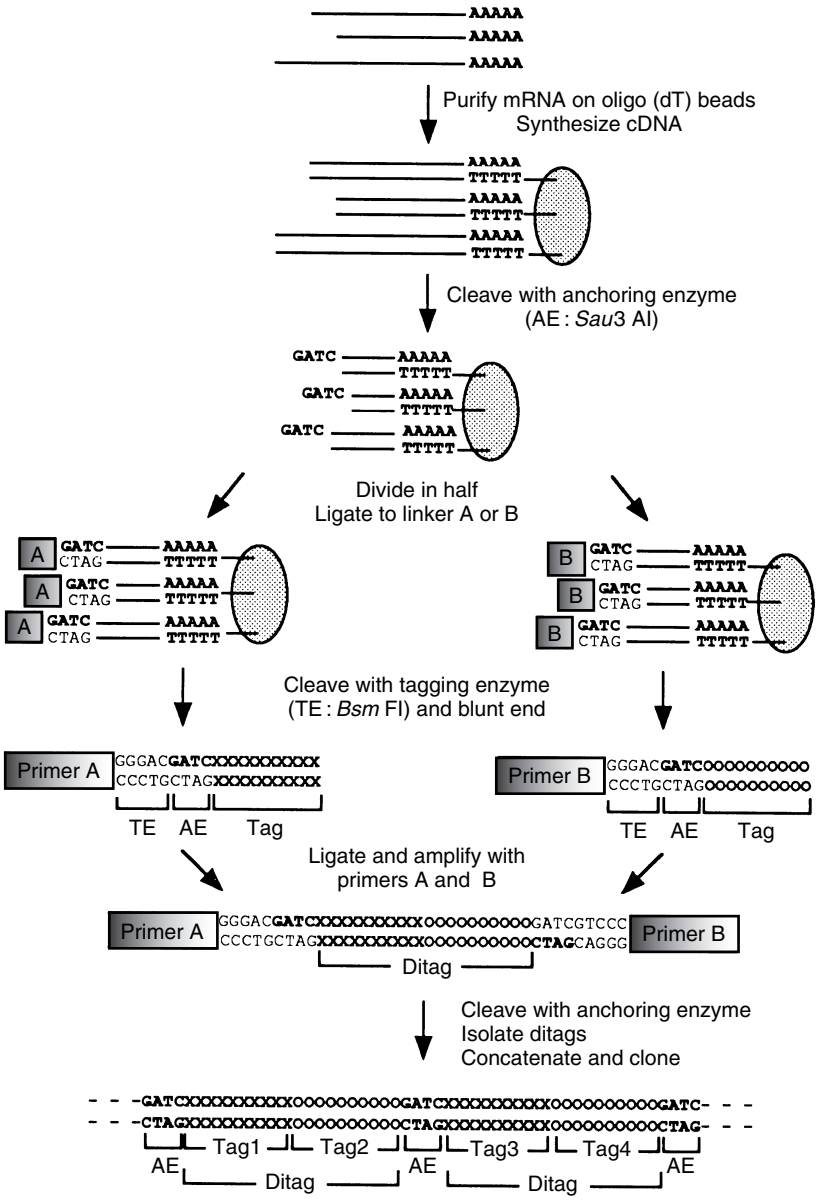

Fig. 1 Outline of procedures for constructing SAGE libraries. Poly(A) RNAs are isolated from tissue lysate using oligo(dT)$_{25}$ covalently linked to paramagnetic beads, and cDNA is synthesized under solid-phase condition. Bold face characters correspond to biologically relevant sequences, whereas light characters represent linker-derived sequences. The anchoring enzyme (AE) is *Sau* 3AI, whereas the tagging enzyme (TE) is *Bsm* FI. See text for details (Reprinted with permission from Cheval, L., Virlon, B., Elalouf, J.-M. (2000) SADE: A Microassay for Serial Analysis of Gene Expression, in: Hunt, S.P., Livesey, F.J. (Eds.) *Functional Genomics: A Practical Approach*, Oxford University Press, Oxford).

Tab. 1 Example of SAGE output (reproduced by courtesy of R. Quere and G. Bertrand, PhD theses, Montpellier University). Comparison between the expression profiles of (**A**) proliferating acute promyelocytic leukemia cells (NB4 human cell line), (**B**) cells incubated for 24 h in the presence of 1 µM retinoic (inducing cell growth arrest and granulocytic differentiation), and (**C**) normal blood granulocytes. SAGE was performed, using *Sau*3AI as anchoring enzyme. Comparison with (**D**) the sum of tag counts for the same genes in a compilation of 260 published SAGE libraries, built from various human tissues using *Nla* III as anchoring enzyme was also performed. These 36 entries represent about 0.7% of the total number of genes (>5000) revealed in this experiment. Examples of ambiguities in tag assignment are provided by *B2M* and *CAPN10*, sharing the same *Sau* 3AI-anchored tag but distinguished with *Nla* III, and by *COX7C* identified only with *Sau* 3AI since its transcript is devoid of *Nla* III restriction site. The upper rows illustrate the detection of differentiation markers. The lowest rows show the case of components of the translation machinery, ribosomal proteins, and elongation factor transcripts, abundant in leukemia cells, but barely detectable in terminally differentiated normal cells.

50 ng of RNA, by adding a loop of RNA amplification in the SAGE protocol as in SAR-SAGE or aRNA-longSAGE. It must be kept in mind that modifications aimed at reducing the amount of starting material may introduce representation biases. When this risk is carefully evaluated, it is possible to build a SAGE library starting from minute amounts of material.

The synthesis of double-stranded cDNA is performed according to classical methods. In the original protocol, a soluble biotinylated oligo(dT) primer was used to initiate the reaction and cDNA fragments were purified at a later step by capture on streptavidin-coated beads. In more recent protocols, oligo(dT) covalently linked to paramagnetic beads were used to bind poly(A) RNA. Performing all subsequent reactions on this solid phase greatly improved the overall yield.

The next step consists of cleaving cDNA by a restriction enzyme with a 4-bp recognition site (SAGE-anchoring enzyme). Only the most 3′ fragment of each cDNA remains on magnetic beads and the other fragments are eliminated. Since the enzyme cleaves every 256 bp (4^4) on average, it is expected to generate a 3′ fragment from the vast majority of cDNAs. The choice of an anchoring enzyme (AE) is limited by the necessity to create a protruding 4-bp single strand, further used to bind a synthetic linker. The most commonly used one is *Nla* III recognizing CATG sites, but *Sau* 3AI (GATC) works equally well. The bead suspension, bearing the purified 3′ cDNA fragments, is then divided in half. Each aliquot is ligated to one of two linkers containing the cognate sequence for the type IIS restriction endonuclease (*Bsm* FI or *Mme* I), used as a tagging enzyme (TE). The enzyme releases DNA fragments, each containing a SAGE tag associated to a synthetic linker.

The two pools of released fragments are ligated to form ditags. For being properly coupled tail to tail, DNA fragments must be blunted on their ''biological'' side and chemically blocked on their ''synthetic'' side. Ditags then serve as templates for amplification by polymerase chain reaction (PCR) with primers specific to each linker. Since there is a small probability of any two tags being assembled twice in the same combination, amplifying randomly assembled ditags rather than separate tags eliminates most PCR biases. Following amplification, the 4-bp restriction enzyme initially used to generate anchoring sites is now used to release the synthetic linkers. Purified ditags, now bearing sticky ends, are concatenated by ligation and the concatemers inserted in a cloning vector.

The SAGE library now consists of a collection of bacterial clones, each one harboring a unique random collection of tags. Before submitting them to sequence analysis, it is advisable to evaluate the average size of concatemers. It is indeed rather difficult to control ligation kinetics and concatemer elongation. Although it has no incidence on individual tag detection and does not alter the overall quality of the analysis, it has a direct effect on the cost and rate of acquisition of data. In some cases, it may be wiser preparing a new reaction rather than analyzing very small concatemers.

Technically, building a SAGE library was perceived as a heavy task, involving multiple steps critical for the success of the overall project. Several laboratories have devoted specific studies to the solution of various problems: efficiency of SAGE adaptor ligation, efficiency of *Bsm*FI digestion, prevention of amplification biases, improved *Nla*III digestion of 102-bp ditags,

synthesis of concatemers and cloning efficiency, easier clone selection. Eventually, the commercial availability of dedicated reagents (Invitrogen Corporation, Carlsbad, CA) greatly facilitated the preparation of SAGE libraries. With all these improvements, the SAGE technology is now being considered in many laboratories as a standard for gene expression profiling.

1.3 Processing Sequence Data

Raw SAGE data are provided as computer files containing the sequences of numerous clones. Merging these files into a unique one, usually in FASTA format, provides a permanent record of the analysis. A dedicated computer program is then needed for parsing this file and identifying individual tag boundaries. Since the first software created at the inception of SAGE in the laboratory of K. Kinzler (Johns Hopkins University, Baltimore, MD, USA), other parsers were developed with more or less extended functions. They usually include the detection of linker artifacts and sequence ambiguities, and must provide a measure of ditag average length. Indeed, type IIS restriction enzymes such as *Bsm* FI yield fragments of variable length. Since tags are ligated tail to tail, delineation of tag ends becomes so difficult in short ditags that they are preferably rejected. This problem has been discussed elsewhere. Ditags with twice the expected length can also be detected in sequence files. Their frequency may help estimate the sequencing error rate, assuming that the apparent loss of the 4-bp anchoring enzyme site defining ditag boundaries results from sequencing errors. If obtained early enough during the sequencing process, this indication may prompt the investigators to improve the quality of the sequencing machine or base calling software. When dealing with already obtained SAGE data, correcting the sequencing error noise requires more complex treatments. Identical ditags can also be observed. In principle, considering the complexity of the transcriptome in eukaryotic cells expressing thousands of genes, there is a low probability, which can be evaluated, to find the same tags associated several times in identical ditags. A low transcriptome complexity, increasing the number of identical ditag, may be observed in terminally differentiated, highly specialized cells. Alternatively, a high frequency of identical ditags may indicate that the cDNA input was not large enough to reproduce the true complexity of the natural mRNA population: this problem may be encountered when sampling minute amounts of biological material. The decision to discard or include repeatedly observed ditags in the calculation of tag frequencies eventually depends on a biologist's appraisal.

While in any case, the ultimate goal is to generate a reliable list of tags along with the number of times they occur, sequence data contain additional information, which, when extracted by appropriate software, provides elements of diagnosis for assessing the quality of SAGE libraries.

1.4 Statistical Analysis of Digital Transcriptomes

Methods for the quantitative analysis of gene expression can be broadly classified into two categories. ''Analog'' methods, using homemade microarrays or commercial DNA chips, are based on the measurement of analogical signals, correlated with the extent of hybridization of labeled transcripts to arrayed cDNAs

or oligonucleotides. ''Digital'' methods are based on tag counting in large collections of ESTs, SAGE, or Massively Parallel Signature Sequencing libraries (MPSS). The quantitative value of both kinds of methods has been thoroughly investigated and it is possible to delineate the limits within which each experimental dataset can be used. Digital profiles can now be interpreted on a sound theoretical framework. In analysis of SAGE data, the first assumption is usually that the number of tags is proportional to the number of cognate transcripts in the original biological sample, implying that each mRNA copy has the same chance of ending up as a tag in the library. The second assumption is that, when prepared for sequence characterization, SAGE tags are picked at random in a highly redundant, unbiased library. The problem of distinguishing biological values from technical errors becomes to set the limits between genuine variation and sampling fluctuation. Focusing on this sampling variability, several tests have been published giving essentially the same values when applied to the comparison of two SAGE libraries. Assessing fluctuations between groups of libraries requires more complex treatments.

1.5 Tag-to-gene Mapping

Identification of the gene transcripts revealed by SAGE tags is independent of experimental data acquisition. It might thus be conceivable to initiate a SAGE project on a given species before having an extensive knowledge of its genome, and indeed, investigations on human cells began several years before completion of the human genome sequencing project. Even when the full-length genome sequence is available, mapping SAGE tags directly to chromosomes is possible only for species with a small compact genome, such as yeast and *Arabidopsis thaliana*. For mammalian species, the size of noncoding regions is such that only LongSAGE (21-bp) tags can be mapped on to the genome. When dealing with conventional 10-bp tags, it is better to start from collections of expressed sequences such as UniGene, maintained at the National Center for Biotechnology Information (NCBI, http://www.ncbi.nlm.nih.gov/). This experimental system organizes GenBank sequences into a nonredundant set of clusters, each one containing sequences that represent a unique gene. A sequence representative of each cluster can be retrieved from UniGene, as well as related information about the biological properties of the corresponding gene.

Using such a collection, an efficient strategy is to prepare a list of putative tags, predicted by performing virtual SAGE *in silico*. Lists of already predicted tags can be retrieved from SAGEmap, another public resource of NCBI dedicated to the dissemination of SAGE data. SAGEmap gives both tag-to-gene and gene-to-tag mapping, and calculates a score indicating the quality of the connection. Lists of predicted and experimental tags are easily recorded in the table format of current relational database management systems, either from commercial (Microsoft Access) or open source (MySQL), so that all tag-to-gene connections can be performed at once. The rate of success obviously depends on the number of well-annotated genes in the species under investigation. In human samples, more than 50% of tag sequences can now be connected immediately to known genes, representing about 70% of the total number of tag counts. The discrepancy between these two values simply reflects the fact that

abundant transcripts correspond more often to already well-known genes.

A small number of genes, which can be predicted, will systematically escape SAGE analysis because their transcript lacks the 4-bp anchoring site required to adapt SAGE linkers. Obviously, they must be studied by other means. A solution would be to prepare two libraries in parallel using each of the two enzymes (*Nla* III and *Sau* 3AI) already selected for their efficiency as anchoring enzymes. Table 1, as well as computer simulation on UniGene sequences, show that identification would then be nearly complete, but with a rather limited benefit compared to the twofold increase of the cost for sequencing analysis.

Another problem is that different genes may share the same tag. Although this risk seems statistically low, real-life examples show that multiple matches are actually observed at a rather high rate. In human samples, this problem results essentially from the presence of retrotransposed repetitive elements (mostly Alu sequences) inserted in the 3′ end of otherwise unrelated transcripts. These sequences can be retrieved from a dedicated database such as RepBase Update (http://www.girinst.org/Repbase_Update.html), and the corresponding tag and gene sequences registered in specific files.

Conversely, a gene may have more than one tag, either as the consequence of alternative splicing or because longer mRNA species encompassing the first polyadenylation site are actually present in cell extracts. The existence of alternative polyadenylation sites increases the number of tags and this phenomenon must be taken into account when analyzing SAGE data.

Upon completion of the tag-to-gene mapping procedure, it is tempting to consider that unmatched tags actually signal yet unknown transcript. However, before developing strategies for their identification, it is necessary to purge SAGE datasets from spurious sequences generated by technical artifacts. Tags matching the mitochondrial genome are sometimes considered as contaminants. However, it is worth mentioning that transcription of the mitochondrial genome produces two polycistronic RNAs (one from each strand) giving rise to a series of poly(A) RNAs. Tags matching the mitochondrial genome are therefore biologically relevant. By contrast, ribosomal RNA fragments may be considered as contaminants, because mRNAs represent a low percentage of the overall nucleic acid cell content. These fragments amounted to up to 1% of the total tag population in libraries generated using the initial SAGE protocol. With more stringent conditions being used for the purification of poly(A) RNAs, their abundance was reduced to less than 0.01% in most libraries. Finally, a significant number of incorrect tags are created by sequencing errors. Typically, SAGE tags are obtained by single-pass sequencing. With 1% of nucleotides determined incorrectly, about 1 of 10 tags will be erroneous. However, since the probability of the same real tag being erroneously sequenced several times is low, the major effect is an increasing number of tags observed at low to moderate frequency. With a small number of SAGE libraries at hand, authors usually discarded tags observed only once. Now that a large number of libraries are publicly available, it is possible to distinguish artifacts from genuine tags of rare transcripts by checking their occurrence in multiple samples. Taken together, technical artifacts essentially increase the apparent number of different tag sequences. However, because their individual frequencies

are low, they alter only marginally the quantification of authentic mRNAs.

As a whole, tag-to-gene mapping can be perceived as a sieving process, in which the list of experimental tags is percolated through multiple filters. At the end of this process, investigators obtain a list of tags identifying authentic mRNAs and a list of tags that are susceptible to revealing the existence of novel transcripts.

2 Making Sense of SAGE Data

2.1 Unmatched Tags and Novel Transcripts: Using SAGE to Annotate the Genome and the Transcriptome

In species with a well-annotated genome, the vast majority of known mRNAs are identified without ambiguity. However, in spite of progress in genome annotation, SAGE libraries often contain unassigned tags susceptible to reveal rarely expressed genes, new alternate transcripts of known genes, genetic variants, or polyadenylated transcripts of noncoding genes.

As could be expected, the characterization of new transcripts proved to be more efficient when using the LongSAGE method instead of the classical one, as shown for the human and more recently for the mouse genome. When dealing with a conventional 10-bp short tag, its assignment to entirely new loci will be easier if it can be matched with a yet unassigned EST, providing an extended probe for experimental investigations and computer searches. When such information is lacking, it is still possible to use the tag itself as a probe, and to amplify an extended cDNA stretch starting from the 10-bp SAGE tag.

With respect to the size of the genome, evaluating the size of the transcriptome remains a controversial issue. Alternative splicing and alternative polyadenylation, each concerning perhaps half the human genes, contribute to increasing the number of transcripts. SAGE can detect alternative exons in the very 3′ end of mRNAs, but does not make distinction between splice variants differing in more 5′ sites. On the contrary, SAGE is highly sensitive to alternative polyadenylation. The existence of transcripts of variable length, seldom registered in current transcript database, has been clearly documented by using dedicated computer programs. These results suggest that nearly half the human genes might generate alternate transcripts, depending on tissue- or disease-specific regulatory mechanisms.

SAGE is sensitive to genetic polymorphism. Alternative tags can be generated by single nucleotide polymorphism (SNP), either because an SNP disrupts the anchoring site of the most commonly observed tag, creates a new anchoring site, or changes the sequence usually registered in databases. A database of human SNP-associated alternative SAGE tags has recently been integrated in SAGE Genie, improving the interpretation of SAGE data.

Detailed analyzes of chromosomes 21 and 22 by massively parallel hybridization on genomic DNA probes revealed a mammalian transcriptome larger than previously estimated. In fact, just as SAGE itself, these strategies made no distinction between conventional mRNAs and noncoding polyadenylated transcripts. The ability of SAGE to reveal such untranslated transcripts deserves interest, considering the regulatory function they may exert.

An initially intriguing observation was that of a subpopulation of tags mapping on to the opposite strand of known mRNAs. For a part, they might be assigned to repetitive elements inserted in opposite orientations in multiple mRNAs. More than one million copies of the approximate 300-bp Alu elements are interspersed in the human genome and a fraction of them are inserted in transcribed 3′-UTRs. Other pairs of tags were found associated with unique pairs of transcripts. Some of them are encoded in trans, the corresponding genes being found on remote loci, while other pairs of tags reveal cis-encoded genes. These observations are corroborated by recent computer searches at the genome level, identifying a large number of contiguous, oppositely oriented genes, potentially able to express complementary mRNAs. SAGE is well adapted for investigating whether such genes are expressed simultaneously, a condition obviously required for them for producing functional double-stranded RNAs.

The detection of genuine tags that were left unpredicted by the analysis of conventional transcript sequences contributes to improving the quality of genome annotation. SAGE can now be considered as more sensitive than EST sequencing for detecting low-abundantly and rarely expressed genes in mammalian genomes.

2.2 From SAGE to Functional Genomics: Linking High-throughput Expression Analysis, Studies on Genome Organization and Complex Biological Networks

The first comprehensive view of a transcriptome was obtained by representing the frequency of SAGE tags on the physical map of yeast chromosomes. More recently, a human transcriptome map, based on the computer-assisted representation of SAGE tags mapping on to chromosomes, has illustrated the power of SAGE for investigating the organization of chromatin and the distribution of genes in actively transcribed regions.

A contemporary challenge is to establish relationships between global variations of gene expression profiles and changes in complex metabolic or signaling networks. Until now, findings in molecular and cell biology were reported in textual form, using an uncontrolled vocabulary, and disseminated in a million publications. The heterogeneity of biological knowledge and, even more critically, the fuzziness of essential concepts including the concept of biological function itself, make the task highly difficult. Collective efforts are being made for calling genes unequivocally (HUGO Gene Nomenclature Committee, http://www.gene.ucl.ac.uk/nomenclature/) and to control the vocabulary used for defining the semantic links that describe functional relations among biological entities (Gene Ontology™ (GO) Consortium: http://www.geneontology.org/). Lists of descriptors provided by this consortium can be linked to SAGE data, so that tags may be automatically classified according to the functional properties of their corresponding genes. Most algorithms for large-scale gene expression analysis were developed to facilitate the interpretation of microarray data. In fact, methods such as association-rules discovery or clustering analysis can be used as well for analyzing SAGE data.

Several interactive Web sites provide synthetic views of an increasing number of networks. For instance, by connecting to the Web site of the Kyoto Encyclopedia of Genes and Genomes (KEGG, http://www.genome.jp/kegg/), it is possible to automatically stain a large number

of metabolic charts according to the results of SAGE and to get in a few hours a synthetic view of events occurring in most metabolic and some signaling pathways.

Interpretation of the set of data generated by each individual laboratory is usually not extensive. Since SAGE data are cumulative, comparisons with remote data may enrich the interpretation of local results. For this purpose, the Gene Expression Omnibus collects expression datasets issued from SAGE and microarray technologies, making them accessible for further analysis and reinterpretation. More specifically, SAGE Genie, a bioinformatic project dedicated to the management of large amounts of experimental SAGE data provides, among other intuitive tools, visualization displayers relating gene expression and tissue localization.

2.3 SAGE, Molecular Classification of Cell Types and Cell Physiology

Conceptually, a given cell type might be defined by its transcriptome, considered as the whole set of genes responsible for its phenotype. However, cells are under constant evolution. They may express functions dictated by proteins whose mRNAs were expressed at a former stage of development, but already catabolized at the time of sampling. Conversely, the presence of a transcript does not always mean that it was being translated at the time of sampling. A gene expression profile must therefore be considered as a snapshot and interpreted as such. With this reservation, transcriptome analysis possesses an advantage over other high-throughput strategies, such as proteome analysis, which, because proteins cannot be amplified, is less sensitive and identifies a smaller number of cell components. Evaluation of SAGE data from a variety of normal and diseased tissues soon provided an enlarged view of the human transcriptomes.

The possibility to work on tiny cell samples was decisive for defining the profile of discrete cell subtypes. Analysis of microdissected anatomical structures provided panoramic views of complex tissues such as kidney (Fig. 2), retina, or brain. Homogeneous samples of circulating cells are more easily purified than cells from solid tissues and numerous blood cell types have now been described by SAGE at the molecular level.

Most biological response modifiers do not act only on rapid cell kinetics through the activation of signaling pathways, but also exert long-lasting effects by changing gene expression patterns. Large-scale transcriptome analysis thus added a new dimension to studies involving the experimental induction of a signaling pathway and the effects of cytokines, hormones, or differentiation inducers.

2.4 SAGE and Disease-induced Alterations of the Transcriptome

It was readily perceived that SAGE offered new possibilities for characterizing global expression profile alterations in infectious diseases, for instance, upon exposition to bacterial toxins or viral infection. However, the major incentive for implementing the SAGE technology came from cancer research. Molecular classification of cancer cells, expected for many years, is now coming of age, opening new perspectives for cancer therapies. The power of SAGE for identifying molecular markers of cancer was rapidly demonstrated, and since the pioneering works, a large number of SAGE libraries have been obtained

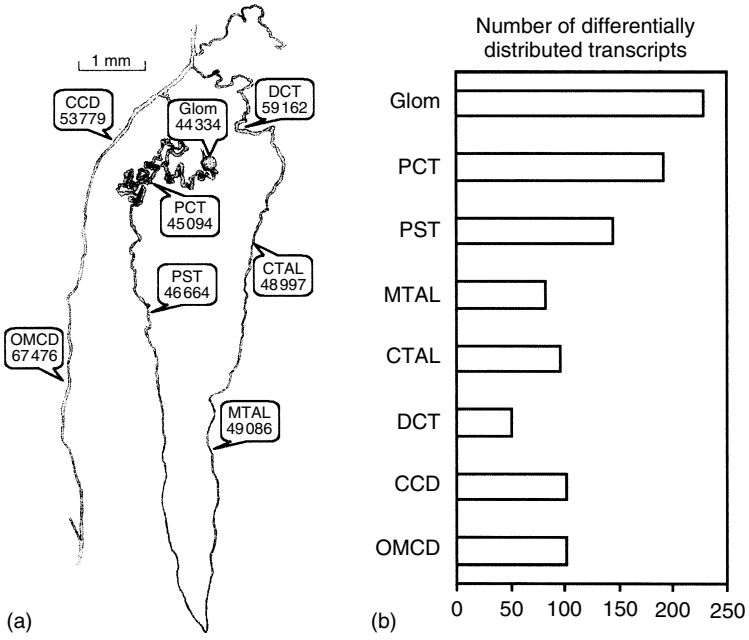

Fig. 2 Transcriptome characterization of individual nephron portions of the human kidney. (a) A microdissected human nephron. Structures analyzed for trancriptome characterization, together with the number of SAGE tags sequenced are indicated. Glom, glomerulus; PCT, proximal convoluted tubule; PST, proximal straight tubule; MTAL, medullary thick ascending limb of Henle's loop; CTAL, cortical thick ascending limb of Henle's loop; DCT,distal convoluted tubule; CCD, cortical collecting duct; OMCD, outer medullary collecting duct. (b) Overview of mRNA differential distribution. The number of mRNAs displaying a significant differential distribution ($p < 0.01$ as compared with three nephron portions) is indicated for each structure. The overall number of heterogeneously distributed transcripts is 998. Data from Chabardes-Garonne, D., Mejean, A., Aude, J.C., et al. (2003) A panoramic view of gene expression in the human kidney, *Proc. Natl. Acad. Sci. U.S.A.* **100**, 13710–13715.

with the purpose of comparing normal cells and their malignant counterparts. SAGE was also used to investigate tumor angiogenesis or drug sensitivity of malignant cells. It is not possible to summarize here all the projects developed since the inception of SAGE. A comprehensive view can be obtained from SAGEmap (http://www.ncbi.nlm.nih.gov/SAGE) and SAGE Genie (http://cgap.nci.nih.gov/SAGE), two components of the Cancer Genome Anatomy Project intended to provide a central database for comparing gene expression profiles in normal and malignant tissues.

3 Perspectives

SAGE was developed at the same time as DNA chip and microarrays technologies.

More recently, MPSS offered an alternative approach to SAGE, but the need for specific equipment limited its use to a small number of laboratories. Each technology has its specific advantages. Methods based on hybridization are well adapted for the comparison of multiple samples, but are limited to the study of the genes represented in the array. SAGE and MPSS are more laborious, but do not require *a priori* knowledge on gene sequences. Moreover, their results are cumulative and comparison between independent datasets are easily performed, while exchanging microarray data requires a complex standardization protocol. Rather than a competing methodology with other global gene expression approaches, it thus seems better considering SAGE as a complementary approach, and the decision to initiate a new SAGE project as depending on the biological problem is under investigation.

SAGE is still receptive to methodological improvements. It is obvious that it will benefit from any progress in DNA sequencing technology that increases the rate of acquisition and reduces the cost of analysis. Until now, the conventional method identified mRNAs by tagging their 3′ end. However, there was still a need for a global method of also identifying transcripts through their 5′ end. Protocols enabling the high-throughput extraction of tags from mRNA 5′ ends have now been published. The 5′-end SAGE is expected to improve the characterization of transcriptional start sites and the functional annotation of poorly known genes.

It is worth noticing that SAGE has already produced a huge amount of experimental results from which latent biological knowledge may be extracted by mining the existing dataset. With the progress of computational biology, the integration of SAGE data in larger information systems, seamlessly coupling data from various sources, opens the way to global analyses on the regulation of gene expression at a higher level of organization. Comparative analysis between man and animal models will be highly useful, and facilitated by the development of new databases such as the Mouse SAGE site (http://mouse.biomed.cas.cz/sage/).

SAGE has already contributed, in conjunction with other methodologies, in achieving a more comprehensive and quantitative picture of transcriptomes. It will probably continue to provide new data until their complete disclosure.

Keywords

Anabolics
Compounds that demonstrate a marked retention of nitrogen through an increase of protein synthesis and a decrease in protein catabolism in the body.

Androgens
Steroid hormones responsible for the primary and secondary sex characteristics of the male, including the development of the vas deferens, prostate, seminal vesicles, and penis.

Antiandrogens
Agents that compete with endogenous androgens for the hormone binding site on the androgen receptor and blocks androgen action.

Dihydrotestosterone
The C_{19} steroid hormone that is the 5α-reduced metabolite of testosterone produced in certain androgen target tissues and is the most potent endogenous androgen.

5α-Reductase Inhibitors
Compounds that inhibit the conversion of testosterone to its more active metabolite dihydrotestosterone.

Selective Androgen Receptor Modulators
Agents that may act as an androgen antagonist or weak agonist in one tissue but act as strong androgen agonist in another tissue type.

Testosterone
The C_{19} steroid hormone that is the predominant circulating androgen in the bloodstream and is produced mainly by the testis.

The steroid testosterone is the major circulating sex hormone of the male and serves as the prototype for the androgens, the anabolic agents, and androgen antagonists. The endogenous androgens are biosynthesized from cholesterol in various tissues in the body; the majority of the circulating androgens are made in the testes under the stimulation of the gonadotropin LH. The reduction of testosterone to dihydrotestosterone is necessary for the androgenic actions of testosterone in androgen target tissues such as the prostate; the oxidation of testosterone by the enzyme aromatase produces estrogens. The androgenic actions of testosterone are due to the binding of dihydrotestosterone to its nuclear receptor, followed by dimerization of the receptor complex and binding to a specific DNA sequence. This binding of the homodimer to the androgen response element leads to gene expression, stimulation of the synthesis of new mRNA, and subsequent protein biosynthesis. The synthetic androgens and anabolics were prepared to impart oral activity to the androgen molecule, to separate the androgenic effects of testosterone from its anabolic effects and to improve upon its biological activities. Drug preparations are used for the treatment of various androgen-deficient diseases, for the therapy of diseases characterized by muscle wasting and protein catabolism, for postoperative adjuvant therapy, and for the treatment of certain hormone-dependent cancers. The two major categories of androgen antagonists are the antiandrogens, which block interactions of androgens with the androgen receptor, and the inhibitors of androgen biosynthesis and metabolism. Such compounds have therapeutic potential in the treatment of acne, virilization in women, hyperplasia and neoplasia of the prostate, and baldness, and for male contraception.

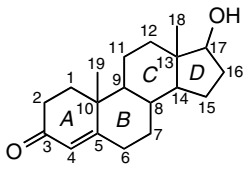
1 Introduction

Androgens are a class of steroids that are responsible for the primary and secondary sex characteristics of the male. In addition, these steroids possess potent anabolic or growth-promoting properties. The general chemical structure of androgens is based upon the androstane C_{19} steroid, consisting of the fused four-ring steroid nucleus (17 carbon atoms, rings A–D) and the two axial methyl groups (carbons 18 and 19) at the A/B and C/D ring junctions. The hormone testosterone (**1**) is the predominant circulating androgen and is produced mainly by the testis. 5α-Dihydrotestosterone (DHT) (**2**) is a 5α-reduced metabolite of testosterone produced in certain androgen target tissues and is the most potent endogenous androgen.

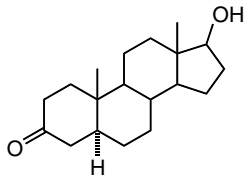
These two steroids and other endogenous androgens influence not only the development and maturation of the male genitalia and sex glands but also affect other tissues such as kidney, liver, and brain. This chapter will discuss the endogenous androgens, synthetic analogs, various anabolic agents, and the androgen antagonists employed in clinical practice or animal husbandry in the United States and elsewhere. Modified androgens that have found use as biochemical or pharmacological tools also are included. More extensive presentations of the topic of androgens, anabolics, and androgen antagonists have appeared in several treatises published over the past three decades.

2 Historical

The role of the testes in the development and maintenance of the male sex characteristics, and the dramatic physiological effects of male castration have been recognized since early time. Berthold was the first to publish in 1849 a report that gonadal transplantation prevented the effects of castration in roosters, suggesting that the testis produced internal secretions exhibiting androgenic effects. However, the elucidation of the molecules of testicular origin responsible for these actions took almost another century. The first report of the isolation of a substance with androgenic activity was made by Butenandt in 1931. The material, isolated in very small quantities from human male urine, was named *androsterone* (**3**). A second weakly androgenic steroid hormone was isolated from male urine in 1934. This substance was named *dehydroepiandrosterone* (**4**) because of its ready chemical transformation and structural similarity to androsterone. A year later, the isolation of the testicular androgenic hormone, testosterone (**1**), was reported, which was 10 times as potent as androsterone in promoting capon comb growth. Shortly after this discovery, the first chemical synthesis of testosterone

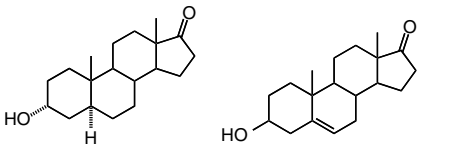


Testosterone (**1**)



5α-Dihydrotestosterone (**2**)

was reported by Butenandt and Hanisch and confirmed by Ruzicka.

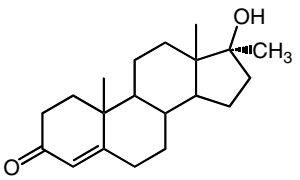


Androsterone (**3**) Dehydroepiandrosterone (**4**)

For many years it was believed that testosterone was the active androgenic hormone in man. In 1968, however, 5α-DHT (**2**), also referred to as *stanolone*, was demonstrated to be the active androgen in target tissues, such as the prostate and seminal vesicles and was formed from testosterone by a reductase present in these tissues. Shortly thereafter a soluble receptor protein was isolated and demonstrated to be specific for DHT and related structures.

The anabolic action of the androgens was first documented by Kochakian and Murlin in 1935. In their experiments, extracts of male urine caused a marked retention of nitrogen when injected into dogs fed a constant diet. Soon afterward testosterone propionate was observed to produce a similar nitrogen-sparing effect in humans. Subsequent clinical studies demonstrated that testosterone was capable of causing a major acceleration of skeletal growth and a marked increase in muscle mass. This action on muscle tissue has been referred to more specifically as the *myotrophic effect*.

The first androgenic-like steroid used for its anabolic properties in humans was testosterone. Unfortunately, its use for this purpose was limited by the inherent androgenicity and the need for parenteral administration. 17α-Methyltestosterone (**5**) was the first androgen discovered to possess oral activity, but it too did not show any apparent separation of androgenic and anabolic activity. The promise of finding a useful, orally effective, anabolic agent free from androgenic side effects prompted numerous clinical and biological studies.



17α-Methyltestosterone (**5**)

3 Endogenous Male Sex Hormones

3.1 Occurrence and Physiological Roles

The hormone testosterone affects many organs in the body. Its most dramatic effects are observed on the primary and secondary sex characteristics of the male. These actions are first manifested in the developing male fetus when the embryonic testis begins to secrete testosterone. Differentiation of the Wolffian ducts into the vas deferens, seminal vesicles, and epididymis occurs under this early androgen influence, as does the development of external genitalia and the prostate. The reductive metabolism of testosterone to 5α-DHT is critical for virilization during this period of fetal development, as dramatically demonstrated in patients with a 5α-reductase deficiency.

At puberty, further development of the sex organs (prostate, penis, seminal vesicles, and vas deferens) is again evident and under the control of androgens. Additionally, the testes now begin to produce mature spermatozoa. Other effects of testosterone, particularly on the secondary sex characteristics, are observed.

Hair growth on the face, arms, legs, and chest is stimulated by this hormone during younger years; in later years, testosterone is responsible for thinning of the hair and recession of the hairline. The larynx develops and a deepening of the voice occurs. The male's skin at puberty thickens, the sebaceous glands proliferate, and the fructose content in human semen increases. Testosterone influences sexual behavior, mood, and aggressiveness of the male at the time of puberty.

In addition to these androgenic properties, testosterone also exhibits anabolic (myotrophic) characteristics. General body growth is initiated, including increased muscle mass and protein synthesis, a loss of subcutaneous fat, and increased skeletal maturation and mineralization. This anabolic action is associated with a marked retention of nitrogen brought about by an increase of protein synthesis and a decrease of protein catabolism. The increase in nitrogen retention is manifested primarily by a decrease in urinary rather than fecal nitrogen excretion and results in a more positive nitrogen balance. For example, intramuscular administration of 25 mg of testosterone propionate twice daily can produce a nitrogen retention to appear within 1 to 3 days, reaching a maximum in about 5 to 8 days. This reduced level of nitrogen excretion may be maintained for at least a month and depends on the patient's nutritional status and diet.

Androgens influence skeletal maturation and mineralization, which is reflected in an increase in skeletal calcium and phosphorus. In various forms of osteoporosis, androgens decrease urinary calcium loss and improve the calcium balance in patients. This effect is not as noticeable in normal patients. Moreover, the various androgen analogs differ markedly in their effects on calcium and phosphorus balance in man. Androgens and their 5β-metabolites (e.g. etiocholanolone) markedly stimulate erythropoiesis, presumably by increasing the production of erythropoietin and by enhancing the responsiveness of erythropoietic tissue to erythropoietin. The effects of androgens on carbohydrate metabolism appear to be minor and secondary to their primary protein anabolic property. The effects on lipid metabolism, on the other hand, seem to be unrelated to this anabolic property. Weakly androgenic metabolites such as androsterone have been found to lower serum cholesterol levels when administered parenterally.

3.2 Biosynthesis

The androgens are secreted not only by the testis but also by the ovary and adrenal cortex. Testosterone is the principal circulating androgen and is formed by the Leydig cells of the testes. Other tissues, such as liver and human prostate, form testosterone from precursors, but this contribution to the androgen pool is minimal. Since dehydroepiandrosterone and androstenedione (see Fig. 2) are secreted by the adrenal cortex and ovary, they indirectly augment the testosterone pool because they can be rapidly converted to testosterone by peripheral tissues.

Plasma testosterone levels for men usually range between 0.61 and 1.1 µg/100 mL and are 5 to 100 times female values. The circulating level of DHT in normal adult men is about one-tenth the testosterone level. Daily testosterone production rates have been estimated to be 4 to 12 mg for young men and 0.5 to 2.9 mg for young women. Although attempts have been made to estimate

the secretion rates for testosterone, these studies are hampered by the number of tissues capable of secreting androgens and the considerable interconversion of the steroids concerned.

The synthesis of androgens in the Leydig cells of the testes is regulated by the gonadotropic hormone, luteinizing hormone (LH), also called *interstitial cell-stimulating hormone* (ICSH). The other pituitary gonadotropin, follicle-stimulating hormone (FSH), acts primarily on the germinal epithelium and is important for sperm development. Both of these pituitary gonadotropins are under the regulation of a decapeptide hormone produced by the hypothalamus. This hypothalamic hormone is luteinizing hormone-releasing hormone (LHRH), also referred to as *gonadotropin-releasing hormone* (GnRH). In adult males, pulsatile secretion of LHRH, and subsequently LH and FSH, occurs at a frequency of 8 to 14 pulses in 24 h. The secretions of these hypothalamic and pituitary hormones are, in turn, regulated by circulating testosterone levels in a negative feedback mechanism. Testosterone will decrease the frequency and amplitude of pulsatile LH secretion, whereas, testosterone and a gonadal peptide, inhibin, are both involved in suppressing the release of FSH.

Our understanding of steroidogenesis in the endocrine organs has advanced considerably during the past three decades, based largely on initial investigations with the adrenal cortex and subsequent studies in the testis and ovary as well. Figure 1 outlines the following sequence of events known to be involved with steroidogenesis in the Leydig cells. LH binds to its receptor located on the surface of the Leydig cell and, via a G-protein-mediated process, activates adenylyl cyclase to result in an increase in intracellular concentrations of cyclic adenosine monophosphate (cAMP). cAMP activates a cAMP-dependent protein kinase,

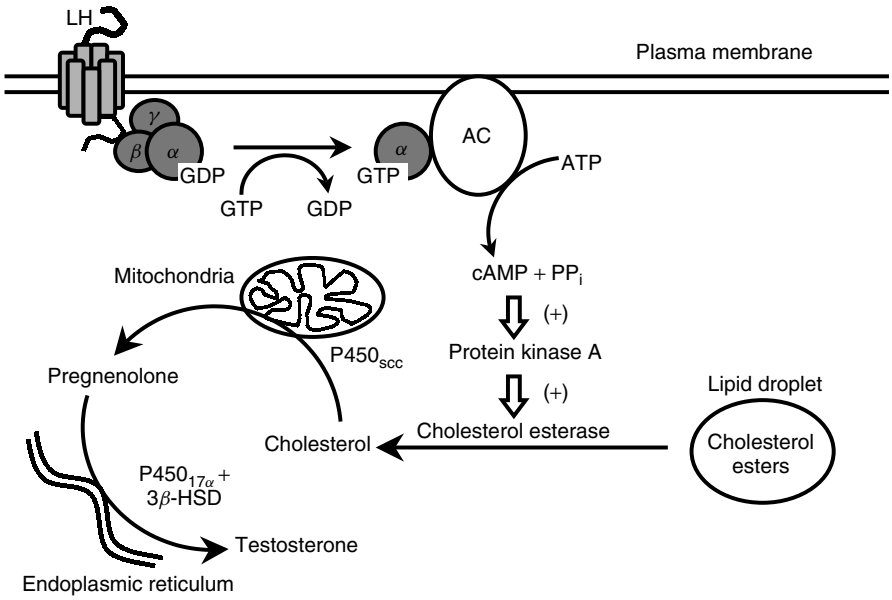


Fig. 1 Cellular events in steroidogenesis in Leydig cell.

which subsequently phosphorylates and activates several enzymes involved in the steroidogenic pathway, including cholesterol esterase and cholesterol side-chain cleavage. Cholesterol esters (present in the cell as a storage form) are converted to free cholesterol by cholesterol esterase, and free cholesterol is translocated to mitochondria. A cytochrome P-450 mixed-function oxidase system, termed *cholesterol side-chain cleavage*, converts cholesterol to pregnenolone. Several nonmitochondrial enzymatic transformations then convert pregnenolone to testosterone, which is secreted.

The conversion of cholesterol (**6**) to pregnenolone (**7**) has been termed the *rate-limiting step* in steroid hormone biosynthesis. The reaction requires NADPH and molecular oxygen and is catalyzed by a cytochrome P-450 enzyme complex termed *cholesterol side-chain cleavage*. This enzyme complex consists of three proteins – cytochrome $P450_{SCC}$ (also called cytochrome P450 11A), adrenodoxin, and adrenodoxin reductase. Three moles of NADPH and oxygen are required to convert one mole of cholesterol into pregnenolone (Fig. 2).

Tracer studies have shown that two major pathways known as the ''4-ene'' and ''5-ene'' pathways are involved in the conversion of pregnenolone to testosterone. Both these pathways and the requisite enzymes are shown in Fig. 2. Earlier studies tended to favor the ''4-ene'' pathway, but more subsequent work has disputed this view and suggests that the ''5-ene'' pathway is quantitatively more important in man. The unconjugated steroids identified in normal males are listed in Table 1 along with the concentration in micrograms per hundred milliliters. All the intermediates of the ''5-ene'' pathway were identified, but progesterone (**8**), an important intermediate of the ''4-ene'' pathway, was not found. In addition, sulfate conjugates were present in significant quantities, especially androst-5-ene-3β,17β-diol 3-monosulfate. The data strongly suggest that this intermediate and its unconjugated form constitute an important precursor of testosterone in man. This view, however, was not supported by a kinetic analysis of the metabolism of androst-5-ene-3β,17β-diol (**12**) in man. Further evidence that the predominant pathway appears to be the ''5-ene'' pathway was provided by *in vitro* studies in human testicular tissues.

Tab. 1 Mean concentration of steroids in spermatic venous plasma from five normal males.

Compound	*Concentration [μg 100 mL^{-1}]*
5-Androstene-3β,17α-diol	4.0
5-Androstene-3β,17β-diol	18.5
Dehydroepiandrosterone	2.2
Androstenedione	2.5
Testosterone	74.0
Pregnenolone	4.8
17α-Hydroxypregnenolone	3.9
17α-Hydroxyprogesterone	6.2

Another important step is the conversion of the C-21 steroids to the C-19 androstene derivatives. Whereas the enzymes for side-chain cleavage are localized in mitochondria, those responsible for cleavage of the $C_{17}-C_{20}$ bond ($C_{17}-C_{20}$ lyase) reside in the endoplasmic reticulum of the cell. Early studies implicated 17α-hydroxypregnenolone (**9**) or 17αhydroxyprogesterone (**10**) as an obligatory intermediate in testosterone biosynthesis, and the $C_{17}-C_{20}$ bond was subsequently cleaved by a second enzymatic process to produce the C-19

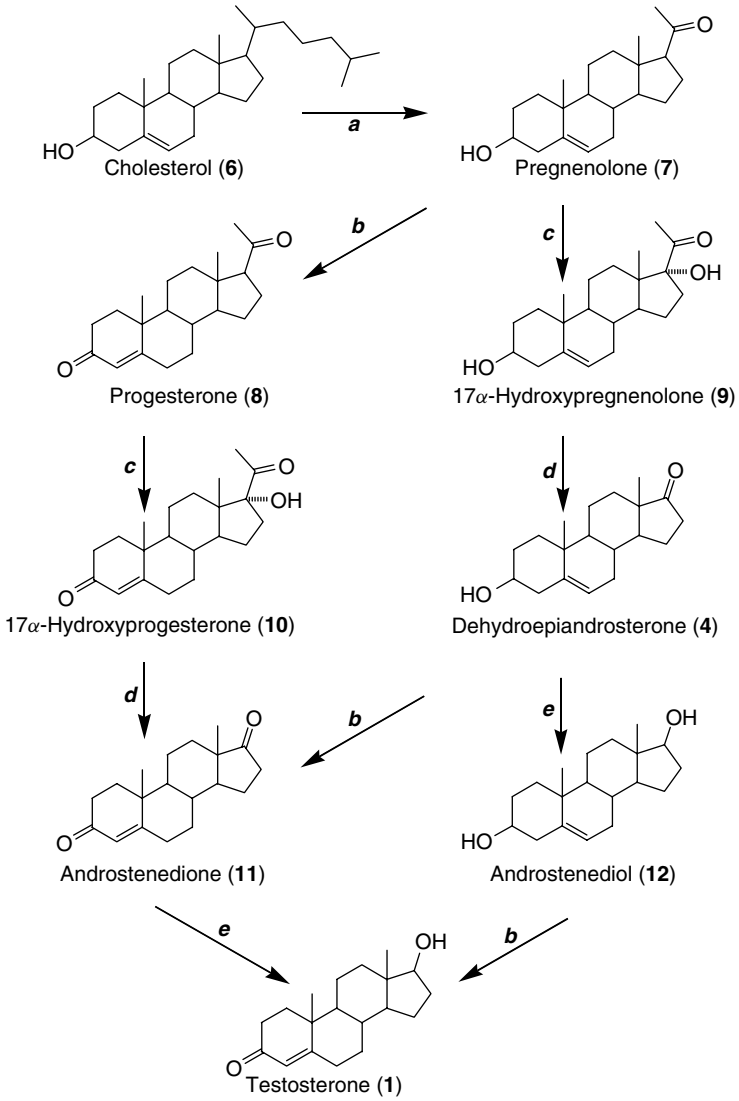

Fig. 2 Enzymatic conversion of cholesterol to testosterone.

androstene molecule. This view of the involvement of two separate enzymes in the conversion of C-21 to C-19 steroids existed until the purification of the proteins in the 1980s. The 17α-hydroxylase/17,20-lyase cytochrome P450 (abbreviated cytochrome P450 17 or cytochrome $P450_{17\alpha}$) was first isolated from neonatal pig testis microsomes, and this cytochrome $P450_{17\alpha}$ possessed both 17α-hydroxylase and 17,20-lyase activity when reconstituted with cytochrome P450 reductase and phospholipid. Identical full-length human cytochrome $P450_{17\alpha}$ cDNA sequences were independently isolated and reported in 1987.

Two additional enzymes are necessary for the formation of testosterone from dehydroepiandrosterone. The first is the 3β-hydroxysteroid dehydrogenase/$\Delta^{4,5}$-isomerase complex, which catalyzes the oxidation of the 3β-hydroxyl group to the 3-ketone and the isomerization of the double bond from C_5-C_6 to C_4-C_5. Again, these processes were originally thought to involve two different enzymes, but purification of the enzymatic activity demonstrated that a single enzyme catalyzes both reactions. The final enzyme in the pathway is the 17β-hydroxysteroid dehydrogenase, which catalyzes the reduction of the 17-ketone to the 17β-alcohol.

3.3 Absorption and Distribution

Although considerable research has been devoted to the biochemical mechanism of action of the natural hormones and the synthesis of modified androgens, little is known about the absorption of these substances. It is well recognized that a steroid hormone might have high intrinsic activity but exerts little or no biological effects because its physicochemical characteristics prevent it from reaching the site of action. This is particularly true in humans, where slow oral absorption or rapid inactivation may greatly reduce the efficacy of a drug. Even though steroids are commonly given by mouth, little is known of their intestinal absorption. One study in rats showed that androstenedione (**11**) was absorbed better than testosterone or 17α-methyltestosterone, and conversion of testosterone to its acetate enhanced absorption. Results with other steroids indicated that lipid solubility was an important factor for intestinal absorption. This may explain the oral activity of certain ethers and esters of testosterone.

Once in the circulatory system by either secretion from the testis or absorption of the administered drug, testosterone and other androgens will reversibly associate with certain plasma proteins, the unbound steroid being the biologically active form. The extent of this binding is dependent on the nature of the proteins and the structural features of the androgen.

The first protein to be studied was albumin, which exhibited a low association constant for testosterone and bound less polar androgens such as androstenedione to a greater extent.

α-Acid glycoprotein (AAG) was shown to bind testosterone with a higher affinity than albumin. A third plasma protein that binds testosterone is corticosteroid-binding α-globulin (CBG). However under normal physiological conditions these plasma proteins are not responsible for extensive binding of androgens in plasma.

A specific protein termed *sex steroid binding β-globulin* (SBG) or testosterone estradiol binding globulin (TEBG) was found in plasma that bound testosterone with a very high affinity. The SBG–sex hormone complex serves several functions, such as transport or carrier system in the bloodstream, storage site or reservoir for the hormones, and protection of the hormone from metabolic transformations. SBG has been purified and contains high affinity, low capacity binding sites for the sex hormones. Dissociation constants of approximately 1×10^{-9} M have been reported for the binding of testosterone and estradiol to SBG and are 2 orders of magnitude less than values reported for the binding of the hormone to the cytosolic receptor protein. The plasma levels of SBG are regulated by the thyroid hormones and remain fairly constant throughout adult

life in both the male and female. SBG is not present in the plasma of all animals. For example, SBG-like activity is notably absent in the rat, and testosterone may be bound in the rat plasma to CBG.

The specificity of the binding of steroids to human SBG has been extensively studied. The presence of a 17β-hydroxyl group is essential for binding to SBG. In addition to testosterone, DHT, 5α-androstane-3β,17β-diol (**19**), and 5α-androstane-3α,17β-diol (**20**) bind with high affinity, and these steroids compete for a common binding site. Binding to SBG is decreased by 17α-substituents such as 17α-methyl and 17α-ethinyl moieties and by unsaturation at C-1 or C-6. Also, 19-nortestosterone derivatives have lower affinity. SBG has been purified to homogeneity by affinity chromatography using a DHT-agarose adsorbent.

Another extracellular carrier protein exhibiting high affinity for testosterone, found in seminiferous fluid and the epididymis, originates in the testis and is called *androgen binding protein* (ABP). This protein is produced by the Sertoli cells on stimulation by FSH and has very similar characteristics to those of plasma SBG produced in the liver.

The absorption of androgens and other steroids from the blood by target cells was usually assumed to occur by a passive diffusion of the molecule through the cell membrane. However, studies in the early 1970s using tissue cultures or tissue slices suggested entry mechanisms for the steroids. Estrogens, glucocorticoids, and androgens exhibit a temperature-dependent uptake into intact target cells, suggesting a protein-mediated process. Among the androgens, DHT exhibited a greater uptake than testosterone in human prostate tissue slices, and it was found that estradiol or androstenedione interfered with this uptake mechanism. In addition, cyproterone competitively inhibited androstenedione, testosterone, and DHT entry, whereas cyproterone acetate enhanced the uptake of these androgens. Little is known about the exit of steroids from target cells; the only reported research has dealt with an active transport of glucocorticoids out of cells.

3.4 Metabolism

For decades, the primary function of metabolism was thought to be the inactivation of testosterone, the increase in hydrophilicity, and the mechanism for the excretion of the steroid into the urine. However, the identification of metabolites of testosterone formed in peripheral tissues and the potent and sometimes different biological activities of these products emphasized the importance of the metabolic transformations of androgens in endocrinology. Two active metabolites of testosterone have received considerable attention – the reductive metabolite 5α-DHT and the oxidative metabolite estradiol (Fig. 3).

3.4.1 Reductive Metabolism

The metabolism of testosterone in a variety of *in vitro* and *in vivo* systems has been reviewed. The principal pathways for reductive metabolism of testosterone in man appear in Fig. 4. Human liver produces a number of metabolites, including androstenedione (**11**), 3β-hydroxy-5α-androstan-17-one (**16**), 5α-androstane-3β,17β-diol (**19**), and 5α-androstane-3α,17β-diol (**20**). Human adrenal preparations, on the other hand, gave 11β-hydroxytestosterone as the major metabolite. (Intestinal metabolism of testosterone is similar to transformations in the

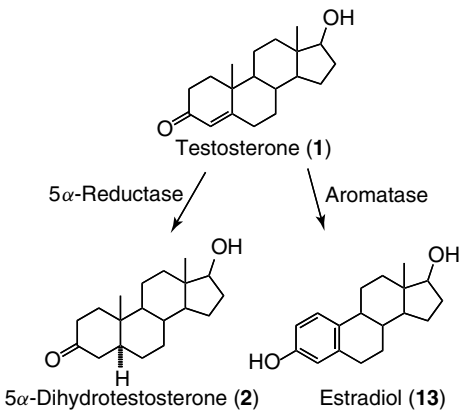

Fig. 3 Enzymatic conversion of testosterone to biologically active metabolites, 5α-dihydrotestosterone and estradiol.

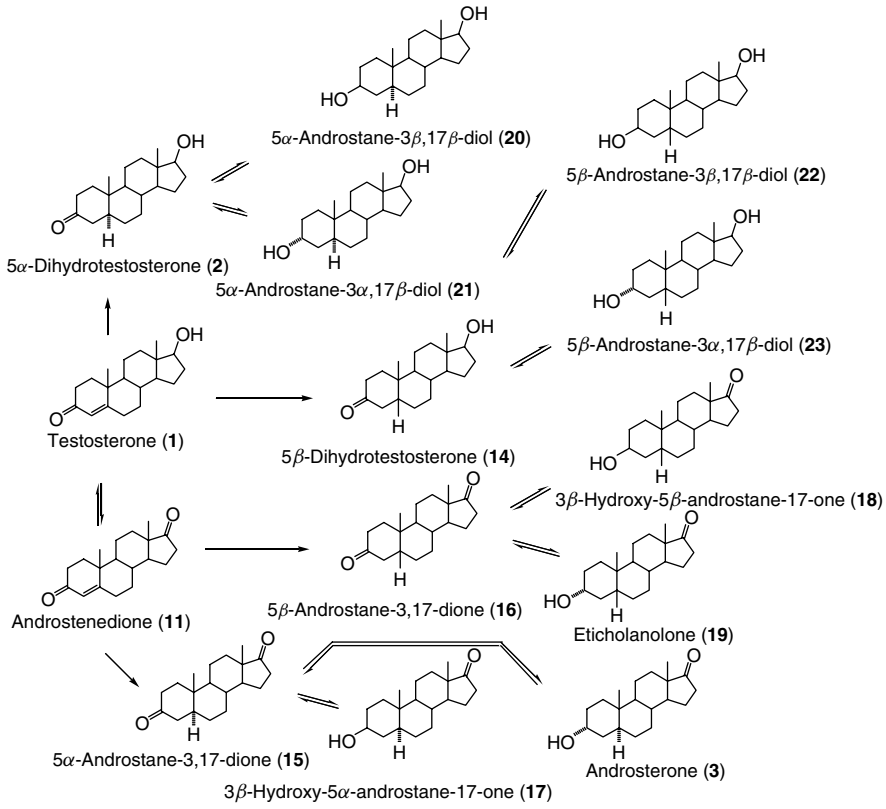

Fig. 4 Reductive metabolites of testosterone.

liver; the major metabolite in lung is androstenedione).

Studies on testosterone metabolism since the late 1960s have centered on steroid transformations by prostatic tissues. Normal prostate, benign prostatic hypertrophy (BPH), and prostatic carcinoma all contain 3α-, 3β-, and 17β-hydroxysteroid dehydrogenases, and 5α- and 5β-reductases, capable of converting testosterone to various metabolites. Prostatic carcinoma metabolizes testosterone more slowly than does BPH or normal prostate. In addition, increased levels of androgens are found in BPH. K. D. Voigt et al. have extensively studied *in vivo* metabolic patterns of androgens in patients with BPH. Tritiated androgens were injected intravenously into these patients 30 min before prostatectomy, and prostatic tissue, tissue from surrounding skeletal muscle, and blood plasma were analyzed for metabolites. The major metabolite of testosterone found in BPH tissues was DHT, with minor amounts of diols isolated. Skeletal muscle and plasma contained primarily unchanged testosterone.

Table 2 lists the urinary metabolites that have been identified following the administration of testosterone to humans (see Fig. 4). These products are excreted as such or in the form of their glucuronide or sulfate conjugates. Androsterone (**3**) and etiocholanolone (**18**), the major urinary metabolites, are excreted predominantly as glucuronides, and only about 10% as sulfates. These conjugates are capable of undergoing further metabolism. Testosterone glucuronide, for example, is metabolized differently from testosterone in man, giving rise mainly to 5β-metabolites. Only a relatively small amount of the urinary 17-ketosteroids is derived from testosterone metabolism. In man at least 67% and in women about 80% or more of the urinary 17-ketosteroids are metabolites of adrenocortical steroids. This explains why a significant increase in testosterone secretion associated with various androgenic syndromes does not usually lead to elevated levels of 17-ketosteroid excretion.

Tab. 2 Urinary metabolites of testosterone.

Metabolite	***Approximate Conversion [%]***
Androsterone	25–50
Etiocholanolone	
5β-Androstane-3α,17β-diol	2
5α-Androstane-3α,17β-diol	1
5α-Androstan-3β-ol-17-one	1
Androst-16-en-3α-ol	0.4
3α,18-Dihydroxy-5β-androstan-17-one	0.3
3α,7β-Dihydroxy-5β-androstan-17-one	Trace
11β-Hydroxytestosterone	Trace
6α-, 6β-Hydroxytestosterone	Trace

Although androsterone and etiocholanolone are the major excretory products, the exact sequence whereby these 17-ketosteroids arise is still not clear. Studies with radiolabeled androst-4-ene-3β,17β-diol and the epimeric 3α-diol in humans showed that oxidation to testosterone was necessary before reduction of the A-ring. Moreover, in rats 5β-androstane-3α,17β-diol (**22**) was the major initial liver metabolite, but this decreased with time with the simultaneous increase of etiocholanolone. This formation of saturated diols agrees with studies using human liver and provides evidence that the initial step in testosterone metabolism is reduction of the α,β-unsaturated ketone to a mixture of diols followed by oxidation to the 17-ketosteroids.

Until 1968, it was generally thought that the excretory metabolites of testosterone were physiologically inert. Subsequent work has shown, however, that etiocholanolone has thermogenic effects when administered to man. Moreover, the hypocholesterolemic effects of parenterally administered androsterone have been described.

The conversion of testosterone to DHT by 5α-reductase has major importance in the mechanism of action of the hormone. This enzymatic activity has been found in the endoplasmic reticulum and in the nuclear membrane of androgen-sensitive cells. In addition, the levels of 5α-reductase are under the control of testosterone and DHT; 5α-reductase activity decreases after castration and can be restored to normal levels of activity with testosterone or DHT administration.

Early biochemical studies of 5α-reductase were performed using a microsomal fraction from rat ventral prostate. The irreversible enzymatic reaction catalyzed by 5α-reductase requires NADPH as a cofactor, which provides the hydrogen for carbon-5. The 5α-reductase from rat ventral prostate tissues exhibited a broad range of substrate specificity for various C_{19} and C_{21} steroids; this broad specificity was also observed in inhibition studies. However, more detailed studies of the enzyme were limited because of the extreme hydrophobic nature of the protein, its instability upon isolation, and its low concentrations in androgen-dependent tissues.

Investigations on the molecular biology of 5α-reductase resulted in the demonstration of two different genes and two different isozymes of the enzyme. The first cDNA isolated and cloned that encoded 5α-reductase was designated type 1, and the second was designated type 2. The gene encoding type 1 is located on chromosome 5, while the gene encoding type 2 is located on chromosome 2. The two human 5α-reductases have approximately 60% sequence homology. These two isozymes differ in their biochemical properties, tissue location, and function. Type 1 5α-reductase exhibits an alkaline pH optimum (6–8.5) and has micromolar affinities for steroid substrates. On the other hand, type 2 5α-reductase has a sharp pH optimum at 4.7–5.5, has higher affinity (lower apparent K_m) for testosterone, and is more sensitive to inhibitors than the type 2 isozyme. The type 2 isozyme is expressed primarily in androgen target tissues, the liver expresses both types, and the type 1 form is expressed in various peripheral tissues. Type 2 5α-reductase appears to be essential for masculine development of the fetal urogenital tract and the external male phenotype, whereas the type 1 isozyme is primarily a catabolic enzyme. In certain cases of human male pseudohermaphroditism, mutations in the type 2 5α-reductase gene are observed and results in significant decreases in DHT levels needed for virilization.

3.4.2 Oxidative Metabolism

Another metabolic transformation of androgens leading to hormonally active compounds is their conversion to estrogens (see Table 3). Estrogens are biosynthesized in the ovaries and placenta and, to a lesser extent, in the testes, adrenals, and certain regions of the brain. The enzyme complex that catalyzes this biosynthesis is referred to as *aromatase*, and the enzymatic activity was first identified by Ryan in the microsomal fraction from human placental tissue. The elucidation of the mechanism of the aromatization reaction began in the early 1960s and continues to receive extensive study. It is a

cytochrome P-450 enzyme complex and requires 3 mol of NADPH and 3 mol of oxygen per mole of substrate. Aromatization proceeds via three successive steps, with the first two steps being hydroxylations. 19-Hydroxyandrostenedione (**23**) was a more active precursor of estrone (**25**) than the substrate androstenedione led to its postulated role in estrogen biosynthesis. This report and numerous studies that followed led to the currently accepted pathway for aromatization, as shown in Fig. 5.

The first two oxidations occur at the C_{19} position, producing the 19-alcohol (**23**) and then the 19-*gem*-diol (**24**), originally isolated as the 19-aldehyde (**25**). The exact mechanism of the last oxidation remains to be fully determined. The final oxidation results in the stereospecific elimination of the 1β and 2β-hydrogen atoms and the concerted elimination of the oxidized C_{19} moiety as formic acid. Investigations using $^{18}O_2$ and isotopically labeled steroidal intermediates failed to show incorporation of the 2β-hydroxyl group into formic acid

Tab. 3 Relative substrate activity in aromatization.

Substrate	***Activity [%]***
C_{19} –Steroids

under enzymatic or nonenzymatic condition and did demonstrate that the oxygen atoms from the first and third oxidation steps are incorporated into formic acid. These results led to the proposal that the last oxidation step is a peroxidative attack at the C_{19} position. Recent computational chemistry approaches of this third step of aromatase catalysis using density functional theory (DFT) and molecular mechanical methods support the final catalytic step involving the 19-*gem*-diol substrate, a cytochrome P450 oxene intermediate, 1β-hydrogen atom abstraction, and release of formic acid.

Incubation of a large number of testosterone analogs with human placental tissue has provided some insight into the structural requirements for aromatization (see Table 4). Whereas androstenedione was converted rapidly to estrone, the 1-dehydro and 19-nor analogs were

metabolized slowly, and the 6-dehydro isomer and saturated 5α-androstane-3,17-dione remained unchanged. Hydroxyl and other substituents at lα, 2β, and 11β interfered with aromatization, whereas similar substituents at 9α and 11α seemingly had no effect. Of the stereoisomers of testosterone, only the 8β,9β,10β-isomer is aromatized, in addition to compounds having the normal configuration (8β, 9α, 10β). Thus, the substrate specificity of aromatase appears to be limited to C_{19} steroids with the 4-en-3-one system. Inhibition studies with various steroids have provided additional insights into the structural requirements for the enzyme; steroidal aromatase inhibitors are described later in Sect. 6.3.3.

Recent research in aromatase has focused on the biochemistry, molecular biology, and regulation of the aromatase protein. Aromatase is a membrane-bound cytochrome P-450 monooxygenase consisting of two proteins – aromatase cytochrome P-450 (P-450_{arom}) and NADPH-cytochrome P-450 reductase. Cytochrome P-450_{arom} is a heme protein that binds the steroid substrate and molecular oxygen and catalyzes the oxidations. The reductase is a flavoprotein, is found ubiquitously in endoplasmic reticulum, and is responsible for transferring reducing equivalents from NADPH to cytochrome P-450_{arom}. Purification of cytochrome P-450_{arom} proved to be very difficult because of its membrane-bound nature, instability, and low tissue concentration. The combination of hydrophobic chromatography using phenyl Sepharose, nonionic detergent, and the presence of micromolar amounts of substrate androstenedione yielded a highly purified and active cytochrome P-450_{arom}, with the highest specific content of 11.5 nmol of cytochrome P-450 per milligram of protein reported. Reconstitution of this cytochrome P-450_{arom} with NADPH-cytochrome P-450 reductase and phospholipid resulted in complete conversion of androstenedione to estrone, thus, demonstrating that one cytochrome P-450 protein catalyzes all three oxidation steps. Knowledge of the molecular biology of aromatase has advanced greatly in the past five years. A full-length cDNA complementary to mRNA encoding cytochrome P-450_{arom} was sequenced and the open reading frame encodes a protein of 503 amino acids. This cDNA sequence was inserted into COS1 monkey kidney cells, and aromatase mRNA and aromatase enzymatic activity were detected in transfected cells. The entire human cytochrome $P450_{arom}$ gene is greater than 70 kb in size and is located on chromosome 15. Clones have been utilized to examine the regulation of aromatase in ovarian, adipose, and breast tissues.

The metabolism of androgens by the mammalian brain has also been investigated under *in vitro* conditions. In rat brain, testosterone is converted to DHT, androstenedione, 5α-androstane-3,17-dione, and 5α-androstane3β,17β-diol. The aromatization of androgens to estrogens was also found to occur in the hypothalamus and the pituitary gland. The full significance of these metabolites on various neuroendocrine functions, such as regulation of gonadotropin secretion and sexual behavior, is not yet fully understood.

3.5 Mechanism of Action

It would indeed be impossible to explain all the varied biological actions of testosterone by one biochemical mechanism. Androgens, as well as the other steroid hormones adrenocorticoids, estrogens, and progestins, exert potent physiological effects on sensitive tissues and yet are

present in the body in only extremely low concentrations (e.g. 0.1–1.0 nM). The majority of investigations concerning the elucidation of the mechanisms of action of androgens have dealt with actions in androgen-dependent tissues and, in particular, the rat ventral prostate. The results of these studies indicate that androgens primarily act in regulating gene expression and protein biosynthesis by formation of a hormone–receptor complex, analogous to the mechanisms of action of estrogens and progestins. Extensive research activities directed at elucidation of the general mechanism of steroid hormone action have been performed for over three decades, and several reviews have appeared on this subject.

Investigations of a selective uptake of androgens by target cells performed in the early 1960s were complicated by low specific activity of the radiolabeled hormones and the rapid metabolic transformations. Nonetheless, it was noted that target cells retained primarily unconjugated metabolites, whereas conjugated metabolites were present in nontarget cells such as blood and liver. With the availability of steroids with high specific activity, later studies demonstrated the selective uptake and retention of androgens by target tissues. In addition, DHT was found to be the steroidal form selectively retained in the nucleus of the rat ventral prostate. This discovery led to the current concept that testosterone is converted by 5α-reductase to DHT, which is the active form of cellular androgen in androgen-dependent tissues.

The rat prostate has been the most widely examined tissue, and current hypotheses on the mode of action of androgens are based largely on these studies (see Fig. 6). The lipophilic steroid hormones are carried in the bloodstream, with the majority of the hormones reversibly bound to serum carrier proteins and a small amount of free steroids. The androgens circulating in the bloodstream are the sources of steroid hormone for androgen action in target tissues. Testosterone, synthesized

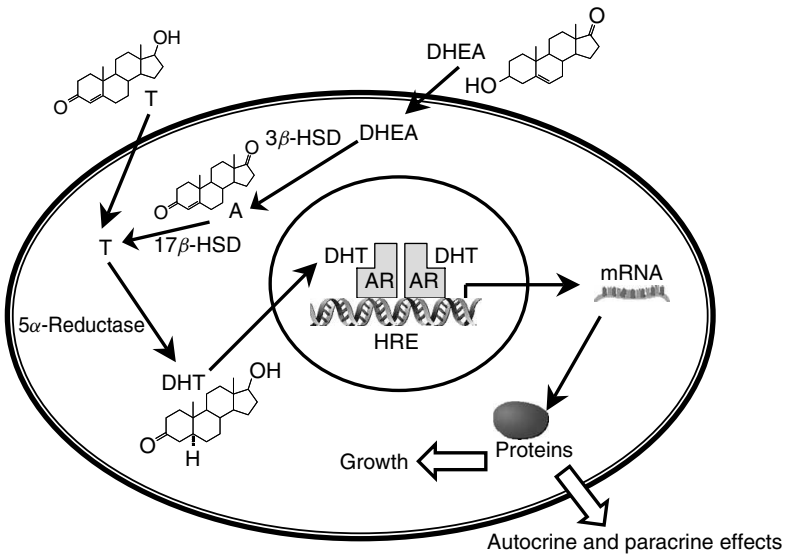

Fig. 6 Mechanism of action of 5α-dihydrotestosterone.

and secreted by the testis, is the major androgen in the blood stream and the primary source of androgen for target tissues in men. Dehydroepiandrosterone (DHEA) and androstenedione also circulate in the bloodstream and are secreted by the adrenal gland under the regulation of adrenocorticotropic hormone (ACTH). DHEA and androstenedione supplement the androgen sources in normal adult men, but these steroids are the important circulating androgens in women. The free circulating androgens steroids passively diffuse through the cell membrane and are converted to the active androgen 5α-DHT within the target cells.

The androgens act on target cells to regulate gene expression and protein biosynthesis via the formation of steroid–receptor complexes. Those cells sensitive to the particular steroid hormone (referred to as *target cells*) contain high-affinity steroid receptor proteins capable of interacting with the steroid. The binding of DHT with the receptor protein is a necessary step in the mechanism of action of the steroid in the prostate cell. Early studies suggested that the steroid receptor proteins were located in the cytosol of target cells and, following formation of the steroid–receptor complex, the steroid–receptor complex translocated into the nucleus of the cell. More recent investigations on androgen action indicate that active, unoccupied receptor proteins are present only in the nucleus of the cell. This nuclear localization of receptor is also observed for estrogens and progestins, while the majority of the glucocorticoid receptor is located in the cytoplasm. In the current model, DHT is formed in the cytoplasm, then enters the nucleus of the cell, and binds to the nuclear steroid receptor protein.

The binding of DHT to the nuclear androgen receptor (AR) initiates a conformational change or activation of the steroid nuclear–receptor complex and results in the formation of a homodimer. The homodimer interacts with particular regions of the cellular DNA, referred to as *androgen-responsive elements* (AREs), and with various nuclear transcriptional factors. Binding of the nuclear steroid–receptor complex to DNA initiates transcription of the DNA sequence to produce messenger RNA (mRNA). Finally, the elevated levels of mRNA lead to an increase in protein synthesis in the endoplasmic reticulum; these proteins include enzymes, receptors, and/or secreted factors that subsequently result in the steroid hormonal response regulating cell function, growth, and differentiation.

Extensive structure–function studies on the androgen receptor or AR have identified regions critical for hormone action. The androgen receptor is encoded by the AR gene located on the X chromosome, and the AR gene is comprised of 8 exons. The human AR contains approximately 900 to 920 amino acids, and the exact length varies because of polymorphisms in the NH_2 terminal of the protein. The primary amino acid sequences of AR, as well as of the various steroid hormone receptors, were deduced from cloned complementary DNAs (cDNAs). The calculated molecular weight of AR is approximately 98 000 kDa based upon amino acid composition; however, the AR is a phosphoprotein and migrates higher at approximately 110 kDa in sodium dodecyl sulfate (SDS) gel electrophoresis. The steroid receptor proteins are part of a larger family of nuclear receptor proteins that also include receptors for vitamin D, thyroid hormones, and retinoids. The overall structure of the androgen receptor (shown in Fig. 7) has

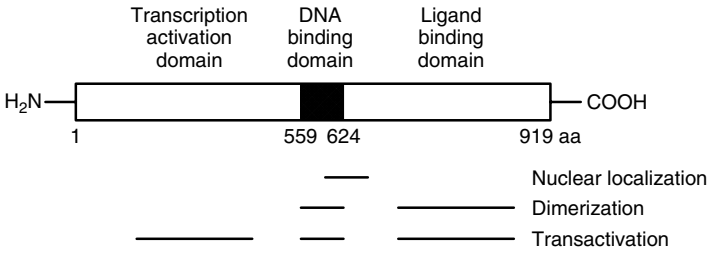

Fig. 7 Schematic diagram of androgen receptor.

strong similarities to the other steroid hormone receptors, with the proteins containing regions that bind to the DNA and bind to the steroid hormone ligand. A high degree of homology (sequence similarities) in the steroid receptors is found in the DNA binding region that interacts with the hormone response elements (HREs). The DNA binding region is rich in cysteine amino acids and chelate zinc ions, forming fingerlike projections called *zinc fingers* that bind to the DNA. The hormone binding domain (or ligand binding domain, LBD) is located on the COOH terminal of the protein. Structure–function studies of cloned receptor proteins also identify regions of the molecules that are important for nuclear localization of the receptor, receptor dimerization, interactions with nuclear transcriptional factors, and activation of gene transcription. Importantly, two regions of the androgen receptor protein are identified as transcriptional activation domains. The domain on the NH_2-terminal region may interact with both coactivators and corepressors, and the COOH-terminal domain initiates transcriptional activation only upon binding of an agonist such as 5α-DHT. The interactions necessary for formation of the steroid–receptor complexes and subsequent activation of gene transcription are complicated, involve multiple protein partners referred to as *coactivators*, and leave many unanswered questions.

Although the tertiary structure of the entire androgen receptor has not been determined, the crystallographic structure of the LBD has recently been reported. The AR LBD consists of an α-helical sandwich, similar to the LBDs reported for other nuclear receptors, and AR LBD contains only 11 helices (no helix 2) and four short β-strands (Fig. 8). Minor differences in the two reported crystallographic structures are likely due to limits of experimental resolution, differences in data interpretation, and the use of different ligands for crystallization. The endogenous ligand DHT (**2**) interacts with helices 3, 5, and 11, and the DHT-bound AR LBD has a single, continuous helix 12 (207). Similar interactions are observed with metribolone (methyltrienolone, **53**); however, helix 12 is split into two shorter helical segments.

Additional information on receptor structure–function has been obtained by analyzing androgen receptor mutations in patients with various forms of androgen resistance and abnormal male sexual development. Two polymorphic regions have been identified in the NH_2-terminal region, encoding a polyglycine repeat and a polyglutamate tract. Currently, these polymorphic regions have not been shown to significantly alter AR levels, stability, or transactivation. These repeats are useful in pedigree analysis of patients. Mutations in the androgen receptor have been identified

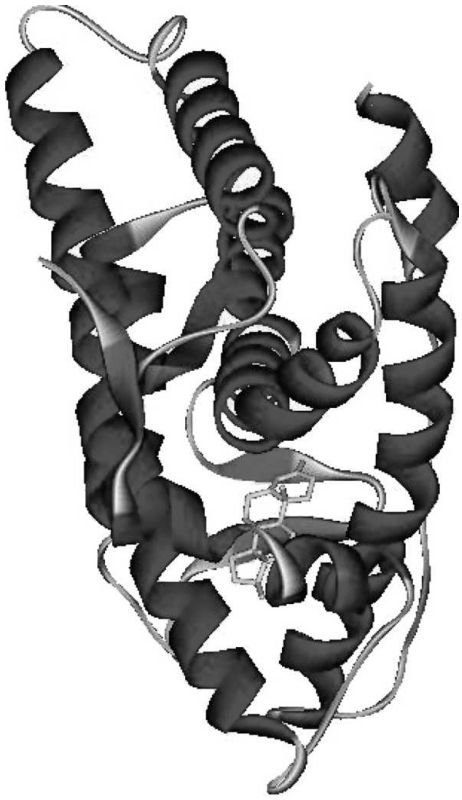

Fig. 8 Ribbon diagram of androgen receptor ligand binding domain (LBD) bound with 5α-dihydrotestosterone. Atomic coordinates were obtained from the Protein Data Bank (PDB ID code 1I37; www.rcsb.org) and displayed using ViewerLite 4.2, Accerlys Inc. 5α-Dihydrotestosterone is illustrated as a stick structure behind Helix 12.

in patients with either partial or full androgen insensitivity syndrome (AIS), with the majority of the mutations identified in exons 4 through 8 encoding the DNA binding domain and the hormone binding domain. Finally, studies with the human LNCaP prostate cancer cell line have provided interesting results regarding receptor protein structure and ligand specificity. The LNCaP cells exhibited enhanced proliferation in the presence of androgens, but these cells also unexpectedly proliferated in the presence of estrogens, progestins, cortisol, or the antiandrogen flutamide. Analysis of the cDNA for the LNCaP androgen receptor revealed that a single base mutation in the LBD was present and resulted in the increased affinity for progesterone and estradiol. The crystallographic structures of the LBD with the T877A mutation confirm that the mutated AR LBD can accommodate larger structures at the C-17 position.

The ultimate action of androgens on target tissues is the stimulation of cellular growth and differentiation through regulation of protein synthesis, and numerous androgen-inducible proteins have been identified. One of the prominent androgen-inducible proteins is prostate-specific antigen (PSA), a serine protease expressed by secretory prostate epithelial cells and utilized as blood test in screening for possible prostate diseases such as prostate cancer. Three AREs have been identified in the promoter regions of the PSA gene. Another androgen-regulated gene examined extensively in rats is the gene encoding the protein probasin, a 20-kDa secretory protein from the rat dorsolateral prostate structurally similar to serum globulins. Other proteins induced by androgens include spermine-binding protein, keratinocyte growth factor or fibroblast growth factor (KGF or FGF-7), androgen-induced growth factor (AIGF or FGF-8), nerve-growth factor, epidermal growth factor, c-myc, protease D, β-glucuronidase, and α_{2u}-globulin. Studies of these proteins suggest that the androgens act by enhancing transcription and/or translation of specific RNAs for the proteins. Also, the androgen receptor represses gene expression of certain proteins

such as glutathione S-transferase, TRMP-2 involved in apoptosis, and cytokines such as interleukin-4, interleukin-5, and γ-interferon.

While most biochemical studies focused on the rat ventral prostate, some researchers began to investigate the presence of cellular receptor proteins in other androgen-sensitive tissues. Androgen receptors have been reported in seminal vesicles, sebaceous gland, testis, epididymis, kidney, submandibular gland, pituitary and hypothalamus, bone marrow, liver, and androgen-sensitive tumors. Although DHT is the active androgen in rat ventral prostate, it is not the only functioning form in other androgen-sensitive cells. In ventral prostate and seminal vesicles, DHT is readily formed. It is metabolized only slowly, however, and therefore can accumulate and bind to receptors. Also, comparison of binding kinetics for testosterone and DHT demonstrated that testosterone dissociates faster, implying extended retention of DHT by the androgen receptor. In other tissues, such as brain or kidney, DHT is not readily formed and is metabolized quickly compared to testosterone. Species variations have also been demonstrated. The most striking example is the finding that 5α-androstane-3α, 17α-diol interacts specifically with cytosolic receptor protein from dog prostate and may be the active androgen in this species. Apparently, the need for a 17β-hydroxyl is not essential in all species.

Thus, current findings indicate that androgen receptor proteins vary in steroid specificity among different tissues from the same species as well as among different species. Nevertheless, the basic molecular mechanism of action of the androgens in androgen-sensitive tissues is consistent with the results of the studies on rat ventral prostate.

The manner whereby the androgens exert their anabolic effects has not been as extensively studied. The conversion of testosterone to DHT has been shown to be insignificant in skeletal and levator ani muscles, suggesting that the androgen-mediated growth of muscle is due to testosterone itself. Classical steroid receptors for testosterone are found in the cytoplasm of the levator ani and quadriceps muscles of the rat. Unlike prostate receptor protein, DHT had a lower affinity than testosterone for this protein. Androgen receptors have also been identified in other muscle tissues as well, including cardiac muscle.

4
Synthetic Androgens

4.1
Current Drugs on the Market

See Table 5.

4.2
Therapeutic Uses and Bioassays

The primary uses of synthetic androgens are the treatment of disorders of testicular function and of cases with decreased testosterone production. Several types of clinical conditions result from testicular dysfunction. Information on the biochemistry and mechanism of action of testosterone that has accumulated over the past 20 years has greatly aided in the elucidation of the underlying pathophysiology of these diseases.

Hypogonadism arises from the inability of the testis to secrete androgens and can be caused by various conditions. These hypogonadal diseases can, in many cases, result in disturbances in

sexual differentiation and function and/or sterility. Primary hypogonadism is the result of a basic disorder in the testes, while secondary hypogonadism results from the failure of pituitary and/or hypothalamic release of gonadotropins and thus diminished stimulation of the testis. Usually primary hypogonadism is not recognized in early childhood (with the exception of cryptorchidism) until the expected time of puberty. This testosterone deficiency is corrected by androgen treatment for several months, at which time the testes are evaluated for possible development. Long-term therapy is necessary if complete testicular failure is present. Patients with Klinefelter's syndrome, a disease in which a genetic male has an extra X chromosome, have low testosterone levels and can also be treated by androgen replacement.

Male pseudohermaphroditism are disorders in which genetically normal men do not undergo normal male development. One type, testicular feminization, is observed in patients who have normal male XY chromosomes, but the male genitalia and accessory sex glands do not develop. Rather, the patients have female external genitalia. These patients are unresponsive to androgens and have defective androgen receptors. Another type of male pseudohermaphroditism results from a deficiency of the enzyme 5α-reductase. Since DHT is necessary for early differentiation and development, the patients again develop female genitalia; later, some masculinization can occur at the time of puberty due to elevated testosterone levels in the blood. A third disorder is Reifenstein syndrome, an incomplete pseudohermaphroditism. In these patients, the androgen levels are normal, 5α-reductase is present, and elevated LH levels are found. Partially deficient androgen receptors are present in these patients. In most cases of male pseudohermaphroditism, androgen replacement has little or no effect and thus steroid treatment is not recommended.

Deficiencies of circulating gonadotropins lead to secondary hypogonadism. This condition can be caused by disorders of the pituitary and/or hypothalamus resulting in diminished secretions of neurohormones. The lack of stimulation of the seminiferous tubules and the Leydig cells due to the low levels of these neurohormones decreases androgen production. Drugs such as the neuroleptic phenothiazines and the stimulant marijuana can also interfere with release of gonadotropins. The use of androgens in secondary hypogonadism is symptomatic.

Synthetic androgens have also been used in women for the treatment of endometriosis, abnormal uterine bleeding, and menopausal symptoms. However, their utility is severely limited by the virilizing side effects of those agents. Two weak androgens, calusterone, and 1-dehydrotestolactone, are used clinically in the treatment of mammary carcinoma in women. The mode of action of these drugs in the treatment of breast cancer is unknown, and is not simply related to their androgenicity. More recent evidence on the ability of these compounds to inhibit estrogen biosynthesis catalyzed by aromatase suggests that they effectively lower estrogen levels *in vivo*.

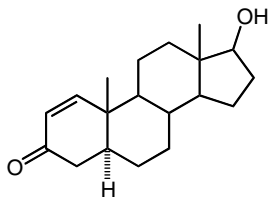
Traditionally, androgens have been assayed by the capon comb growth method and by the use of the seminal vesicles and prostate organs of the rodent. An increase in weight and/or growth of the capon comb have been used to denote androgenic activity following injection or topical application of a solution of the test compound in oil. A number of minor modifications of this test have been

described. The increase in weight of the seminal vesicles and the ventral prostate of the immature castrated male rat has provided another measure of androgenic potency. The test compound is administered either intramuscularly or orally, and the weight of the target organs is compared with those of control animals. *In vitro* evaluation of the relative affinity of potential androgens for the androgen receptor has also become an important tool in assessing biological activity of androgens.

4.3 Structure–Activity Relationships for Androgens

4.3.1 Early Modifications

Most of the early structure–activity relationship studies concerned minor modifications of testosterone and other naturally occurring androgens. Studies in animals and humans showed the 17β-hydroxyl function to be essential for androgenic and anabolic activity. In certain cases, esterification of the 17β-hydroxyl group not only enhanced but also prolonged the anabolic and androgenic properties. The 1-dehydro isomer of testosterone (**28**) and related compounds are potent androgenic and anabolic steroids.

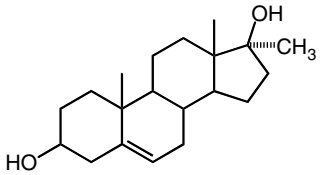


(**28**)

Reduction of the A-ring functional groups has variable effects on activity. For example, conversion of testosterone to DHT has little effect or may increase potency in a variety of bioassay systems. On the other hand, changing the A/B trans stereochemistry of known androgens such as androsterone (**3**) and DHT to the A/B *cis*-etiocholanolone (**18**) and 17β-hydroxy-5β-androstan-3-one (**13**), respectively, drastically reduces both the anabolic and androgenic properties. These observations established the importance of the A/B trans ring juncture for activity.

4.3.2 Methylated Derivatives

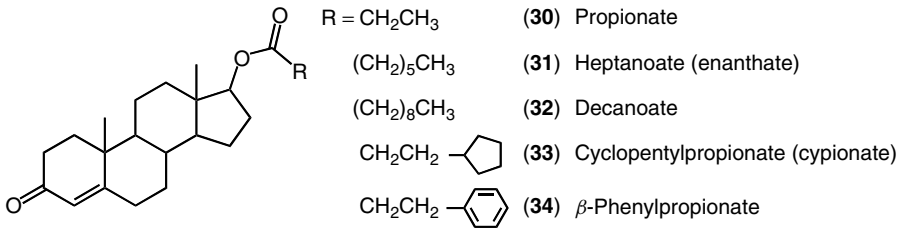
The discovery that C-17α-methylation conferred oral activity on testosterone prompted the synthesis of additional C-17α-substituted analogs. Increasing the chain length beyond methyl invariably led to a decrease in activity. As a result of these studies, however, 17α-methylandrost-5-ene-3β,17β-diol (methandriol, **29**) was widely evaluated in humans as an anabolic agent. Clinical studies showed no advantage of methandriol over 17α-methyltestosterone (**5**).



(**29**)

4.3.3 Ester Derivatives

As early as 1936 it was known that esterification of testosterone markedly prolonged the activity of this androgen when it was administered parenterally. This modification enhances the lipid solubility of the steroid and, after injection, permits a local depot effect. The acyl moiety is usually derived from a long-chain aliphatic or arylaliphatic acid such as propionic, heptanoic



(enanthoic), decanoic, cyclopentylpropionic (cypionic), or β-phenylpropionic acid (**30**–**34**).

4.3.4 Halo Derivatives

In general, the preparation of halogenated testosterone derivatives has been therapeutically unrewarding. 4-Chloro-17β-hydroxyandrost-4-en-3-one (chlorotestosterone, **35**) and its derivatives are the only chlorinated androgens that have been used clinically, albeit sparingly. The introduction of a 9α-fluoro and an 11β-hydroxy substitutent (analogous to synthetic glucocorticoids) gives 9α-fluoro-11β,17β-dihydroxy-17α-methylandrost-4-en-3-one (fluoxymesterone, Halotestin, **36**), which is an orally active androgen exhibiting approximately fourfold greater oral activity than 17α-methyltestosterone. Early clinical studies with fluoxymesterone indicated an anabolic potency that was 11 times that of the unhalogenated derivative. Nitrogen balance studies, however, revealed an activity only 3 times that of 17α-methyltestosterone. Because of the lack of any substantial separation of anabolic and androgenic activity, halotestin is used primarily as an orally effective androgen, particularly in the treatment of mammary carcinoma.

4.3.5 Other Androgen Derivatives

Several synthetic steroids having weak androgenic activity are being utilized in patients. 7β,17α-Dimethyltestosterone (calusterone, **37**) and 1-dehydrotestolactone (Testlac, **38**) are very weak androgenic agents that have been used in the treatment of advanced metastatic breast cancer.

4.3.6 Summary of Structure–Activity Relationships

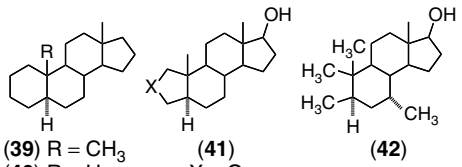
As with other areas of medicinal chemistry, the desire to relate chemical structure to androgenic activity has attracted the attention of numerous investigators. Although it is often difficult to interrelate biological results from different laboratories, androgenicity data from the same laboratory afford useful information. In evaluating the data, one must be careful to note not only the animal model employed, but also the mode of administration. For example, marked differences in androgenic activity can be found when compounds are evaluated in the chick comb assay (local application) as opposed to the rat ventral prostate assay (subcutaneous or oral). The chick comb assay measures ''local androgenicity'' and is believed to minimize such factors as absorption, tissue distribution, and metabolism, which complicate the interpretation of *in vivo* data in terms of hormone–receptor interactions.

Furthermore, although the rat assays correlate well with what one eventually finds in humans, few studies of comparative pharmacology have been performed. Indeed, DHT may not be the principal mediator of androgenicity in all species. For example, a cytosol receptor protein has been found in normal and hyperplastic canine prostate that is specific for 5α-androstane-3α,17α-diol.

Since the presence of the 17β-hydroxyl group was demonstrated very early to be an important feature for androgenic activity in rodents, most investigators interested in structure–activity relationships maintained this function and modified other parts of the testosterone molecule. Three observations can be made on the basis of these studies: (1) The 1-dehydro isomer of testosterone is at least as active as testosterone; (2) the 1- and 4-keto isomers of testosterone and DHT have variable activity; (3) the 2-keto isomers of testosterone and DHT consistently lack appreciable activity.

The oxygen function at position 3 could be removed from testosterone with little reduction in androgenic activity, while removal of the hydroxyl group from position 17 sharply reduced the androgenicity. As a continuation of these studies, the hydrocarbon nucleus, 5α-androstane (**39**), was synthesized. It too was found to possess androgenicity when applied topically or given intramuscularly in the chick comb assay, albeit at high doses. On the other hand, it was learned later that the 19-nor analog, 5α-estrane (**40**), had less than 1% of the androgenic activity of testosterone propionate in castrated male rats.

The relative androgenicity of the isomeric A-ring olefins of 3-deoxy testosterones was the order $\Delta^1 > \Delta^2 > \Delta^3 > \Delta^4$. The Δ^2-isomer displayed the greatest anabolic activity and the best anabolic-to-androgenic ratio. On the basis that sulfur is bioisosteric with CH=CH, the thia, seleno, and tellurio androstanes were synthesized, which displayed androgenic activity. When the heteroatom was oxygen, however, the compound **(41)** was essentially devoid of



(**39**) R = CH_3
(**40**) R = H

(**41**)
X = O

(**42**)

androgenicity. The oxygen analog was said to be inactive because oxygen is isosteric with CH_2 rather than $CH_2{=}CH_2$. Thus, a minimum ring size was found to be required for activity. When the oxygen atom was introduced as part of a six-membered A-ring, an active androgen resulted.

As with the case of the double-bond isomers, the position of the oxygen atom was found to be important. The substitution of oxygen at C-2 gives rise to the most active compound, and the order of activity was $2 > 3 \gg 4$. The full steroid nucleus is not essential for androgen activity, since 7α-methyl 1,4-seco-2,3-bisnor-5α-androstan-17β-ol (**42**) has 50% of the anabolic activity of testosterone.

Both 14-dehydrotestosterone and the corresponding 19-nor analog were found to be potent androgens when applied topically. An extension of this series ascertained the effect of introducing a 7α-methyl. The results of this study are listed in Table 4, in terms of percentage increases in the weights of chick combs, rat ventral prostates, and rat levator ani induced by the test compounds as related to a similar dose of testosterone, the responses to the latter being described as 100%.

The effects of either 7α-methyl or 14- dehydro modification are more pronounced for 19-nortestosterone than for testosterone. The 14-dehydro modification had a greater effect on local androgenicity, whereas 7α-methylation had a more positive effect on systemic androgenicity. A marked synergism resulted when both the 14-dehydro and 7α-methyl modifications were present. The resultant compound, 7α-methyl-14-dehydro-19-nortestosterone, represents one of the most potent androgens reported to date.

The characterization of a specific receptor protein in androgen target tissues has made it possible to directly analyze the receptor affinity of various testosterone analogs. Table 6 shows the receptor affinity and androgenic activity of a variety of androgens relative to DHT. The ability of the various steroids to be retained by prostate nuclei is also indicated. As would be expected, the receptor affinity data did not necessarily correlate with the systemic androgenicity. In some cases, such as with 7α-methyl-19-nortestosterone, there was good agreement. Such was not the case, however, for 19-nortestosterone. Table 7 summarizes their findings. Whereas the importance of the A/B trans ring fusion

14-Dehydrotestosterone	4.4×10^8
14-Dehydro-19-nortestosterone	5.9×10^8
7α-CH_3-14-Dehydro-19-nortestosterone	5.0×10^8

and 17β-hydroxyl prevailed, the data failed to demonstrate the potency previously noted for 7α-methyl-14-dehydro-19-nortestosterone. Moreover, 19-nortestosterone displayed a receptor affinity greater than that of DHT, yet its androgenicity is much less than DHTs.

These differences in correlations between receptor assays and *in vivo* data should not cloud the importance of the receptor studies. The receptor assays measure affinity for the receptor protein, and this property is shared by androgens as well as antiandrogens. Moreover, such assays cannot predict the disposition and metabolic fate of an androgen following administration. Figure 9 contains a summary of the structure–activity relationships for androgens.

4.4 Absorption, Distribution, and Metabolism

Numerous factors are involved in the absorption, distribution, and metabolism of the synthetic androgens and the physicochemical properties of these steroids greatly influence the pharmacokinetic parameters. The lipid solubility of a synthetic steroid is an important factor in its intestinal absorption. The acetate ester of testosterone demonstrated enhanced absorption from the gastrointestinal tract over both testosterone and 17α-methyltestosterone. Injected solutions of testosterone in oil result in the rapid absorption of the hormone from the injection site; however, rapid metabolism greatly decreases the biological effects of the injected testosterone. The esters of testosterone are much more nonpolar and, when injected intramuscularly, are absorbed more slowly. As a result, the commercial preparations of testosterone propionate are administered

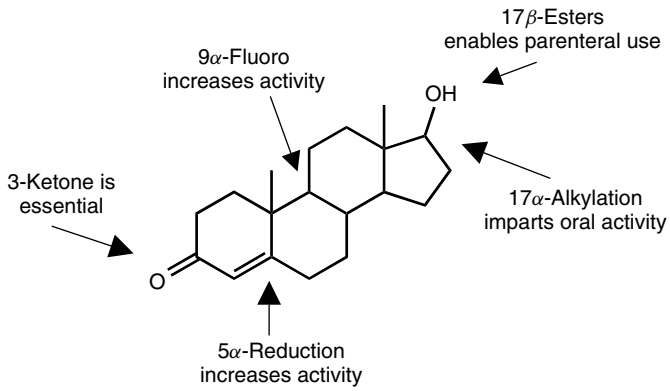

Fig. 9 Summary of structure–activity relationships for androgens.

every 2 or 3 days. Increasing the size of the ester functionality enables the testosterone esters such as the ethanate or cypionate to be given in a depot injection lasting 2 to 4 weeks.

Once absorbed, the steroids are transported in the circulation primarily in a protein-bound complex. Testosterone and other androgens are reversibly associated with certain plasma proteins and the unbound fraction can be absorbed into target cells to exert its action. The structure-binding relationships of the natural and synthetic androgens to sex SBG have been extensively investigated. A 17α-hydroxyl group is essential for binding and the presence of a 17α-substituent such as the 17α-methyl moiety decreases its affinity. The 5α-reduced androgens bind with the highest affinity. A much smaller quantity of the androgen is bound to other plasma proteins, principally albumin and CBG or transcortin.

The metabolism of the synthetic androgens is similar to that of testosterone. The introduction of the 17α-methyl group greatly retards the metabolism, thus providing oral activity. Reduction of the 4-en-3-one system in synthetic androgens to give the various α- and β-isomers occurs *in vivo*. Finally, aromatization of the A-ring can also occur. One analog that demonstrates an alternate metabolic pattern is 4-chlorotestosterone, which in humans gave rise to an allylic alcohol, 4-chloro-3α-hydroxyandrost-4-en-17-one. A number of other halogenated testosterone derivatives subsequently were found to take this abnormal reduction path *in vitro*. It was proposed that fluorine or chlorine substituents at the 2-, 4-, or 6- position in testosterone interfere with the usual α,β-unsaturated ketone resonance so that the C-3 carbonyl electronically resembles a saturated ketone.

4.5 Toxicities

The use of androgens in women and children can often result in virilizing or masculinizing side effects. In boys, an acceleration of the sexual maturation is seen, while in girls and women growth of facial hair and deepening of the voice can be observed. These effects are reversible when medication is stopped; however, prolonged treatment can produce effects that are irreversible. Inhibition of gonadotropin secretion by the pituitary can also occur in patients receiving androgens.

Both males and females experience salt and water retention resulting in edema. This edema can be treated by either maintaining a low-salt diet or by using diuretic agents. Liver problems are also encountered with some of the synthetic androgens. Clinical jaundice and cholestasis can develop after the use of the 17α-alkylated products. Various clinical laboratory tests for hepatic function such as bilirubin concentrations, sulfobromophthalein retention, and glutamate transaminase and alkaline phosphatase activities are affected by these androgen analogs.

5 Anabolic Agents

5.1 Current Drugs on the Market

See Table 8.

5.2 Therapeutic Uses and Bioassays

Many synthetic analogs of testosterone were prepared in order to separate the anabolic activity of the C_{19} steroids from

Tab. 8

Generic name (structure)	*Trade name*	*US manufacturer*	*Chemical class*	*Dose*
Nandrolone decanonate (**43**)	Deca-Durabolin	Organon	Estrane	Injection (in oil): 100 mg mL^{-1} 200 mg mL^{-1}
Oxandrolone (**65**)	Oxandrin	Gynex	Androstane	Tablets: 2.5 mg
Oxymetholone (**63**)	Anadrol-50	Syntex	Androstane	Tablets: 50 mg
Stanozolol (**75**)	Winstrol	Winthrop Pharm	Androstane	Tablets: 2 mg

their androgenic activity. Although the goal of a pure synthetic anabolic that retains no androgenic activity has not been accomplished, numerous preparations are now available on the market that have high anabolic/androgenic ratios.

The primary criterion for assessing anabolic activity of a compound is the demonstration of a marked retention of nitrogen. This nitrogen-retaining effect is the result of an increase in protein synthesis and a decrease in protein catabolism in the body. Thus, the urinary nitrogen excretion, particularly urea excretion, is greatly diminished. The castrated male rat serves as the most sensitive animal model for nitrogen retention, although other animals have been utilized. Another bioassay for anabolic activity involves examination of the increase in mass of the levator ani muscle of the rat upon administration of an anabolic agent. This measure of myotrophic effect correlates well with the nitrogen retention bioassay and the two are usually performed in the determination of anabolic activity.

Anabolic steroids exert other effects on the body as well. Skeletal mineralization and bone maturation are enhanced by androgens and anabolics. These agents will decrease calcium excretion by the kidney and result in increased deposition of both calcium and phosphorus in bone. Androgenic and anabolic agents also can influence red blood cell formation. Two mechanisms of action of this erythropoiesis-involving increased erythropoietin production and enhanced responsiveness of the tissue have been described.

These various biological activities of the anabolics have prompted the use of these agents in treatment protocols, with varying success. Clinical trials have demonstrated the effectiveness of the anabolic steroids in inducing muscle growth and development in some diseases. Anabolic steroids are effective in the symptomatic treatment of various malnourished states due to their ability to increase protein synthesis and decrease protein catabolism. Treatment of diseases such as malabsorption, anorexia nervosa, emaciation, and malnutrition as a result of psychoses includes dietary supplements, appetite stimulants, and anabolics. Improved postoperative recovery with adjunctive use of anabolic agents has been demonstrated in numerous clinical studies. However, their usefulness in other diseases such as muscular dystrophies and atrophies and in geriatrics has not been observed.

Anabolic steroids also have the ability to lower serum lipid levels *in vivo*. The most

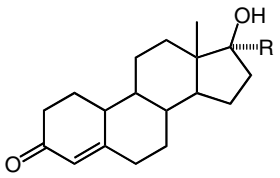
widely studied agent is oxandrolone, which dramatically lowers serum triglycerides and, to a lesser extent, cholesterol levels at pharmacological doses. The proposed mechanism of this hypolipidemic effect includes both an inhibition of triglyceride synthesis and an increased clearance of the triglycerides. The androgenic side effects of the anabolics and the lack of superiority over conventional hypolipidemic agents have curtailed its use for treatment of these conditions.

The stimulation of erythropoiesis by anabolics has resulted in the use of these agents for the treatment of various anemias. Anemias arising from deficiencies of the bone marrow are particularly responsive to pharmacological doses of anabolic agents. Treatment of aplastic anemia with anabolics and corticosteroids has been proven effective. Secondary anemias resulting from inflammation, renal disease, or neoplasia are also responsive to anabolic steroid administration. Synthetic anabolics have been prescribed for women with osteoporosis and for children with delayed growth. These applications have produced limited success; however, the virilizing side effects severely limit their usefulness, particularly in children.

The methods employed to determine the anabolic or myotrophic properties of steroids are based on an increase in nitrogen retention and/or muscle mass in various laboratory animals. The castrated male rat is presently the most widely used and most sensitive laboratory animal for nitrogen balance studies. Dogs and ovariectomized monkeys have also been employed. Although it is generally agreed that variations in urinary nitrogen excretion relate to an increase or decrease in protein synthesis, nitrogen balance assays are not without their limitations. This is partly because such studies fail to describe the shifts in organ protein and measure only the overall status of nitrogen retention in the animal.

The easily accessible levator ani muscle of the rat has provided a valuable index for measuring the myotrophic activity of steroidal hormones. By comparing the weight of levator ani muscle, seminal vesicles, and ventral prostate with controls, one can obtain a ratio of anabolic-to-androgenic activity. There also appears to be some correlation between the levator ani response and urinary nitrogen retention. A modification of this muscle assay utilizes the parabiotic rat and allows for the simultaneous measurement of pituitary gonadotropic inhibition and myotrophic activity. The suitability of the levator ani assay has been questioned for the possibility that its growth is more a result of androgenic sensitivity than of any steroid-induced myotrophic effect. Thus, this assay is usually performed in conjunction with nitrogen balance studies or acceleration of body growth.

Finally, the myotrophic effects have also led to the use and the abuse of these agents by athletes. Conflicting reports on the effectiveness of anabolics to increase strength and power in healthy males have resulted from clinical trials. Several groups reported no significant differences between groups of male college-age students receiving anabolics and weight training and those groups receiving placebo plus the weight training in double-blind studies. Other reports cited some improvement in strength and power, but they utilized small numbers of subjects or were only single blind studies. ''Supraphysiologic'' doses of anabolics have demonstrated enhancement of muscle size and strength. Overall, the consensus of these various studies are that anabolic steroids provide only limited improvement in strength and



R = H (**43**) Nandrolone
R = CH_3 (**44**) Normethandrone
R = CH_2CH_3 (**45**) Norethandrone

power in healthy males. Anabolic steroids also exhibit an anticatabolic effect, that is, reversing the catabolic effects of glucocorticoids released in response to stress. Such effects would enable individuals to recover more quickly following strenuous workouts. An alarming percentage of amateur and professional athletes utilize anabolic steroids, which are readily available ''on the street.'' The use of these steroids for increasing strength and power is banned in intercollegiate and international sports, and very sensitive assays (radioimmunoassay (RIA), gas chromatography-mass spectrometry (GS-MS)) have been developed for measuring anabolic levels in urine and blood. Nonetheless, the recent discovery of ''designer steroids'' such as tetrahydrogestrinone (THG), a new chemical entity synthesized specifically for illicit anabolic use to avoid standard antidoping tests, is an alarming trend and highlights the importance of aggressive detection approaches for monitoring drug doping in sports.

5.3 Structure–Activity Relationships for Anabolics

5.3.1 19-Nor Derivatives

An important step toward developing an anabolic agent with minimal androgenicity occurred when 19-nortestosterone (17β-hydroxyestr-4-en-3-one, nandrolone, **43**) was found to be as myotrophic but only about 0.1 as androgenic as testosterone. This observation prompted the synthesis and evaluation of a variety of 19-norsteroids, including the 17α-methyl (normethandrone, **44**) and the 17α-ethyl (norethandrolone, **45**) homologs of 19-nortestosterone.

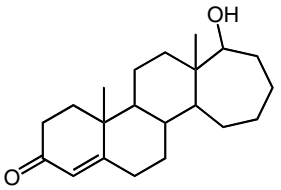
Nandrolone in the form of a variety of esters (such as decanoate and β-phenylpropionate) and norethandrolone have been widely used clinically. The latter, under the name Nilevar®, was the first agent to be marketed in the United States as an anabolic steroid. Androgenic and progestational side effects, however, led to its eventual replacement by other agents.

Nonetheless, these studies did stimulate the synthesis of other norsteroids. Interestingly, both 18-nortestosterone and 18,19-bisnortestosterone were essentially devoid of both androgenic and anabolic properties. Contraction of the B-ring led to B-norsteroids, which were also lacking in androgenicity, but unlike the foregoing, this modification led to compounds with antiandrogenic activity.

Of the number of homoandrostane derivatives (those having one or more additional methylene groups included in normal tetracyclic ring system) that have been synthesized, only B-homo and D-homodihydrotestosterone have shown appreciable androgenic activity. A D-bishomo analog (**46**) was reported to be weakly androgenic.

5.3.2 Dehydro Derivatives

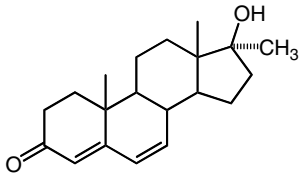
The marked enhancement in biological activity afforded by introduction of a double bond at C_1 of cortisone and hydrocortisone



(**46**)

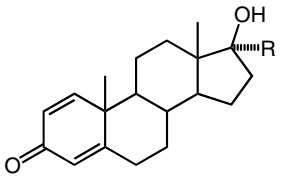
prompted similar transformations in the androgens. The acetate of 17β-hydroxyandrosta-1,4-dien-3-one (**47**) was as myotrophic as testosterone propionate but was much less androgenic. Furthermore, 17α-methyl-17β-hydroxyandrosta-1,4-dien-3-one (methandrostenolone, **48**) had 1 to 2 times the oral potency of 17α-methyltestosterone in the rat nitrogen retention and levator ani muscle assays. In clinical studies, methandrostenolone produced a marked anabolic effect when given orally at doses of 1.25 to 10 mg daily and was several times more potent than 17α-methyltestosterone.

In contrast with the 1-dehydro analogs, introduction of an additional double bond at the 6-position (**49**) markedly decreased both androgenic and myotrophic activity in the rat. Moreover, removal of the C_{19}-methyl, inversion of the configuration at C_9 and C_{10} and at C_8 and C_{10}, and reduction of the C_3-ketone failed to improve the biological properties.



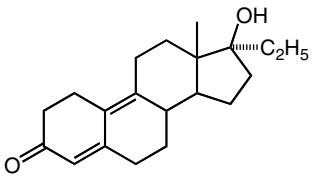
(**49**)

On the other hand, introduction of unsaturation into the B-, C-, and D-rings has given rise to compounds with significant androgenic or anabolic activity. Ethyldienolone (**50**), for example, displayed an anabolic-to-androgenic ratio of 5 and was slightly more active than methyltestosterone when both were given orally. Introduction of a 14–15 double bond (**51**) increased androgenicity when compared with testosterone by local application in the chick comb assay. On the other hand, there was a 25% decrease in androgenicity when measured by the rat ventral prostate following subcutaneous administration. Conversion to the 19-nor analog (**52**) increased

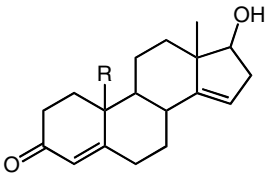


R = H (**47**)
R = CH_3 (**48**)

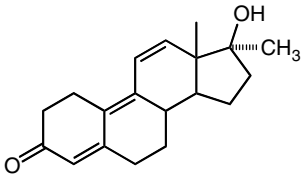
Methandrostenolone



(**50**)



(**51**) R = CH_3
(**52**) R = H



(**53**)

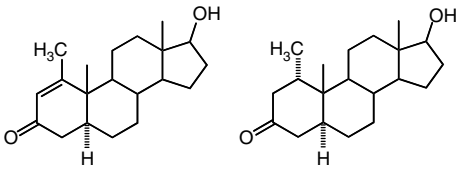
androgenicity, but the anabolic activity was significantly enhanced.

Of a variety of triene analogs of testosterone that have been tested, only 17α-methyl-17β-hydroxyestra-4,9,11-trien-3-one (methyltrienolone, **53**) showed significant activity in rats. Surprisingly, this compound had 300 times the anabolic and 60 times the androgenic potency of 17α-methyltestosterone when administered orally to castrated male rats. In this instance, however, the potent hormonal properties on rats did not correlate with later studies in humans. One study in patients with advanced breast cancer found methyltrienolone to have weak androgenicity and to produce severe hepatic dysfunction at very low doses.

5.3.3 Alkylated Analogs

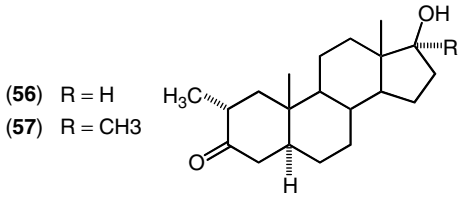
An extensive effort has been directed toward assessing the physiological effect of replacing hydrogen with alkyl groups at most positions of the steroid molecule. Although methyl substitution at C_3, C_4, C_5, C_6, C_{1l}, and C_{16} has generally led to compounds with low anabolic and androgenic activity, similar substitutions at C_1, C_2, C_7, and C_{18} have afforded derivatives of clinical significance.

1-Methyl-17β-hydroxy-5α-androst-l-en-3-one (**54**) as the acetate (methenolone acetate) was about 5 times as myotrophic, but only 0.1 as androgenic, as testosterone propionate in animals. In addition, this compound or the free alcohol represented one of the few instances of a C_{17} nonalkylated steroid that possessed significant oral anabolic activity in animals and in man. This effect may be related to the slow *in vivo* oxidation of the 17β-hydroxyl group when compared with testosterone. At a daily dose of 300 mg, methenolone acetate caused little virilization. By contrast, the dihydro analog, 1α-methyl-17β-hydroxy-5α-androstan-3-one (mesterolone, **55**), was found to possess significant oral androgenic activity in the cockscomb test and in clinical assays. A comparison of the anabolic and androgenic activity of (**54**) with its A-ring congeners revealed that the double bond was necessary at C_1 for anabolic activity. For example, 1α-methyl-17β-hydroxyandrost-4-en-3-one had a much lower activity. Furthermore, either reduction of the C_3 carbonyl group of (**55**) or removal of the C_{19} methyl group greatly reduced both anabolic and androgenic activity in this series.



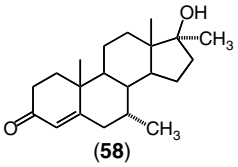
Methenolone (**54**) Mesterolone (**55**)

Among the C_2-alkylated testosterone analogs, 2α-methyl-5α-androstan-17β-ol-3-one (drostanolone, **56**) and its 17α-methylated homolog (**57**) have displayed anabolic activity both in animals and in man. In contrast, 2,2-dimethyl and 2-methylenetestosterone or their derivatives showed only low anabolic or androgenic activity in animals. The most interest in drostanolone has been in relation to its potential as an antitumor agent with decreased masculinizing propensity.

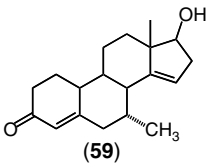


7α,17α-Dimethyltestosterone (bolasterone, **58**) had 6.6 times the oral anabolic

potency of 17α-methyltestosterone in rats. Similar activity was observed in man at 1 to 2 mg day^{-1} without many of the usual side effects. Moreover, the corresponding 19-nor derivative was 41 times as active as 17α-methyltestosterone as an oral myotrophic agent in the rat. 7α-Methyl-14-dehydro-19-nortestosterone (**59**) was found to be approximately 1000 times as active as testosterone in the chick comb assay and about 100 times as active as testosterone in the ventral prostate assay.

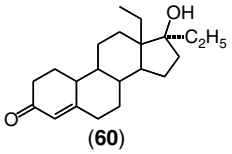


(**58**)

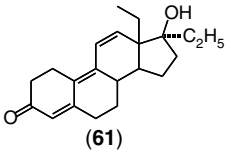


(**59**)

Certain totally synthetic 18-ethylgonane derivatives possessed pronounced anabolic activity. Similar to other 19-norsteroids, 13β,17α-diethyl-17β-hydroxygon-4-en-3-one (norbolethone, **60**) was found to be a potent anabolic agent in animals and in man. Since it is prepared by total synthesis, the product is isolated and marketed as the racemic DL-mixture. The hormonal activity resides in the D-enantiomer.



(**60**)

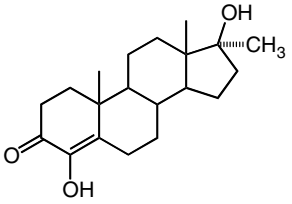


(**61**)

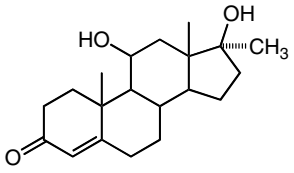
Tetrahydrogestrinone or THG (**61**), a "designer steroid" for illicit anabolic use, is synthesized from the progestin, gestrinone, by reduction of the 17α-ethinyl group. THG demonstrates potent androgenic and progestational activity in *in vitro* receptor bioassay systems. No animal or human studies with THG are known, since this agent was never prepared as a pharmaceutical for medical or veterinary use.

5.3.4 Hydroxy and Mercapto Derivatives

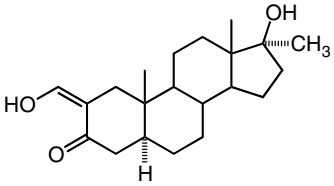
Testosterone has been hydroxylated at virtually every position on the steroid nucleus. For the most part, nearly all these substances possess no more than weak myotrophic and androgenic properties. Two striking exceptions to this, however, are 4-hydroxy- and 11β-hydroxytestosterones. 4-Hydroxy-17α-methyltestosterone (oxymesterone, **62**), for instance, had 3 to 5 times the myotrophic and 0.5 times the androgenic activity of 17α-methyltestosterone in the rat. In clinical studies, oxymesterone produced nitrogen retention in adults at a daily dose of 20 to 40 mg, and no adverse liver function was observed. Introduction of an 11β-hydroxyl group in many instances resulted in a favorable effect on biological activity. 11β-Hydroxy-17α-methyltestosterone (**63**) was more anabolic in the rat than 17α-methyltestosterone and 1.5 times as myotrophic in humans.



(**62**)



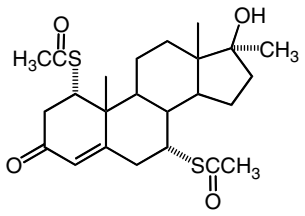
(**63**)



(**64**)

One of the most widely studied anabolic steroids has been 2-hydroxymethylene-17α-methyl-5α-androstan-17β-ol-3-one (oxymetholone, **64**). In animals, it was found to be 3 times as anabolic and 0.5 times as androgenic as 17α-methyltestosterone. Clinical studies confirmed these results.

The substitution of a mercapto for a hydroxyl group has generally resulted in decreased activity. However the introduction of a thioacetyl group at C_1 and C_7 of 17α-methyltestosterone afforded lα,7α-bis(acetylthio)-17α-methyl-17β-hydroxyandrost-4-en-3-one (thiomesterone, **65**), a compound with significant activity. Thiomesterone was 4.5 times as myotrophic and 0.6 times as androgenic as 17α-methyltestosterone in the rat and has been used clinically as an anabolic agent.



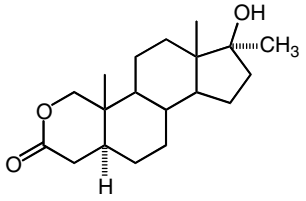
(**65**)

Moreover, numerous 7α-alkylthio androgens have exhibited anabolic-androgenic activity similar to that of testosterone propionate when administered subcutaneously. Even though no clinically useful androgen resulted, similar 7α-substitutions were advantageous in the development of radioimmunoassays now employed in clinical laboratories. In addition, certain 7α-arylthioandrost-4-ene-3,17-diones are effective inhibitors of estrogen biosynthesis (see Sect. 6.3.3).

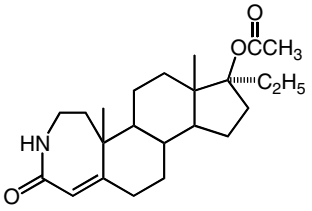
5.3.5 Oxa, Thia, and Aza Derivatives

A number of androgen analogs in which an oxygen atom replaces one of the methylene groups in the steroid nucleus have been synthesized and biologically evaluated. Of these derivatives, 17β-hydroxy-17αmethyl-2-oxa-5α-androstan-3-one (oxandrolone, **66**) was 3 times as anabolic and only 0.24 times as androgenic as 17α-methyltestosterone in the oral levator ani assay. By contrast, only minimal responses were obtained following intramuscular administration. The 2-thia and 2-aza analogs were essentially devoid of activity by both routes. The 3-aza-A-homoandrostene derivative (**67**) displayed only 5% the anabolic-to-androgenic activity of methyltestosterone.

The clinical anabolic potency of oxandrolone was considerably more active than 17α-methyltestosterone and provided perceptible nitrogen sparing at a dose as low as 0.6 mg day^{-1}. Moreover, at dosages of 0.25 to 0.5 mg kg^{-1}, oxandrolone was effective as a growth-promoting agent without producing the androgenically induced bone maturation. Because of this



(**66**)

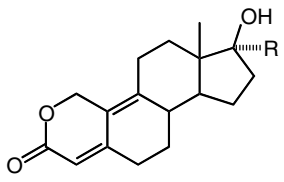


(**67**)

favorable separation of anabolic from androgenic effects, oxandrolone has been one of the most widely studied anabolic steroids. Its potential utility in various clinical hyperlipidemias was discussed in Sect. 5.2.

The significant hormonal activity noted for estra-4,9-dien-3-ones such as (**50**) (see Sect. 5.3.2) prompted the synthesis of the 2-oxa bioisosteres in this series. Despite the lack of a 17α-methyl group, (**68**) had 93 times the oral anabolic activity of 17α-methyltestosterone. It was also 2.7 times as androgenic. As might be expected, the corresponding 17α-methyl derivative, (**69**), was the most active substance in this series. It had 550 times the myotrophic and 47 times the androgenic effect of 17α-methyltestosterone. These two compounds differed dramatically in progestational activity, however. The activity of (**68**) was only 0.1 times, whereas the activity of (**69**) was 100 times that of progesterone in the Clauberg assay. The pronounced oral activity of (**68**) suggests that it is not a substrate for the 17β-alcohol dehydrogenase and represents an interesting finding.

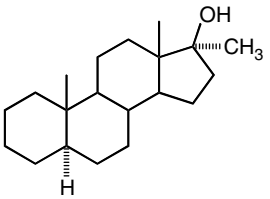
(**68**) R = H
(**69**) R = CH_3



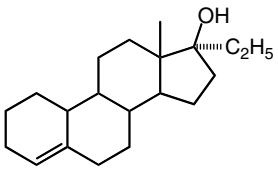
5.3.6 Deoxy and Heterocyclic-fused Analogs

Early studies indicated that the 17β-hydroxyl group and the 3-keto group were essential for maximum androgenic activity. On the basis of this observation, the C_3 oxygen function was removed in the hope of decreasing the androgenic potency while maintaining anabolic activity. Unfortunately, the results failed to substantiate the rationale, and 17α-methyl-5α-androstan-17β-ol (**70**) was found to be a potent androgen in animals and humans. However, this substance is extensively metabolized to the 3-keto derivative by rabbit liver homogenate. Other deoxy analogs of testosterone have been synthesized and tested. A 19-nor derivative, 17α-ethylestr-4-en-17β-ol (estrenol, **71**) had at least 4 times the anabolic and 0.25 times the androgenic activity of 17α-methyltestosterone in animals and was effective in humans at a daily dose of 3 to 5 mg. In addition, 17α-methyl-5α-androst-2-en-17β-ol (**72**) offered a good separation of anabolic from androgenic activity.

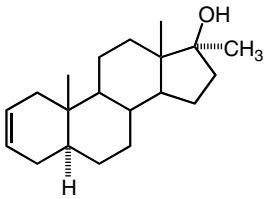
Since sulfur is considered to be isosteric with $-CH{=}CH-$, the 2-thia-A-nor-5α-androstane derivatives such as (**73**) possessed high androgenic and anabolic activity and served to verify that steric rather than electronic factors are important in connection with the structural requirements at C-2 and/or C-3 in androgens. Interestingly, the selenium and tellurium isosteres in the same series were found to



(**70**)

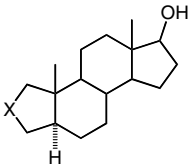


(**71**)

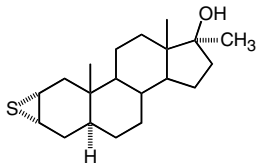


(**72**)

have good androgenic activity. Moreover, experiments with a ^{75} Se-labeled analog have shown (**74**) to selectively bind with the specific cytosol receptor for DHT in rat prostate.



(**73**) X = S
(**74**) X = Se

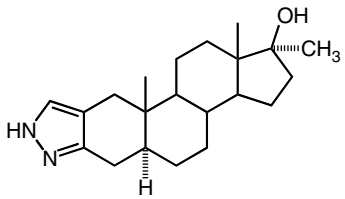


(**75**)

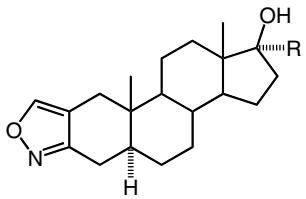
The high biological activity noted for the 3-deoxy androstanes prompted numerous investigators to fuse various systems to the A-ring. The simplest such changes were 2,3-epoxy, 2,3-cyclopropano, and 2,3-epithioandrostanes. The 2α,3α-cyclopropano-5α-androstan-17β-ol was as active as testosterone propionate as an anabolic agent. While the epoxides had little or no biological activity, certain of the episulfides possessed pronounced anabolic/androgenic activity. For example, 2,3α-epithio-17α-methyl-5α-androstan17β-ol (**75**) was found to have approximately equal androgenic and 11 times the anabolic activity of methyltestosterone after oral administration to rats. The 2,3-β-episulfide, on the other hand, was much less active. 2,3α-Epithio-5α-androstan17β-ol has been shown to have long-acting antiestrogenic activity, as well as some beneficial effects in the treatment of mammary carcinoma.

Other heterocyclic androstane derivatives have included the pyrazoles. Thus, 17β-hydroxy-17α-methylandrostano[3,2-*c*] pyrazole (stanozolol, **76**) was 10 times as active as 17α-methyltestosterone in improving nitrogen retention in rats. The myotrophic activity, however, was only twice that of 17α-methyltestosterone. Stanozolol at a dose of 6 mg day^{-1} produced an adequate anabolic response with no lasting adverse side effects.

The high activity of the pyrazoles instigated the synthesis of other heterocyclic fused androstane derivatives including isoxazoles, thiazoles, pyridines, pyrimidines, pteridines, oxadiazoles, pyrroles, indoles, and triazoles. One of the most potent was 17α-methylandrostan-17β-ol[2,3-*d*]isoxazole (androisoxazol, **77**), which exhibited an oral anabolic-to-androgenic ratio of 40. The corresponding 17α-ethynyl analog (danazol, **78**) has been of most interest clinically. This compound has impeded androgenic activity and inhibits pituitary gonadotropin secretion. Since it depresses blood levels of androgens and gonadotropins, it has been studied as an antifertility agent in males. At doses of 200 or 600 mg daily, danazol lowered plasma testosterone and androstenedione levels, and this effect was dose related. In addition to an inhibition in gonadotropin release, a direct inhibition of Leydig cell



(**76**)



(**77**) R = H
(**78**) R = C≡CH

androgen synthesis was observed. Other studies have shown danazol to be effective for the treatment of endometriosis, benign fibrocystic mastitis, and precocious puberty. Several reports have appeared relating to its disposition and metabolic fate.

5.3.7 Esters and Ethers

Since esterification of testosterone markedly prolonged its activity, it was only natural that this approach to drug latentiation would be extended to the anabolic steroids. The acyl moiety is usually derived from a long-chain aliphatic or arylaliphatic acid such as heptanoic (enanthoic), decanoic, cyclopentylpropionic, and β-phenylpropionic. For example, no less than 12 esters of 19-nortestosterone (nandrolone) have been used clinically as long-acting anabolic agents.

In the case of nandrolone, the duration of action and the anabolic-to-androgenic ratio increased with the chain length of the ester group. The decanoate and laurate esters, for instance, were active 6 weeks after injection. Clinically, nandrolone decanoate appeared to be the most practical, since a dose of 25 to 100 mg/week produced marked nitrogen retention.

Since the 17α-alkyl group has been implicated as the cause of the hepatotoxic side effects of oral preparations, the effect of esterification on oral efficacy has attracted attention. For example, esterification of DHT with short chain fatty acids resulted in oral anabolic and androgenic activity in rats. Moreover, esters of methenolone possessed appreciable oral anabolic activity. Unfortunately, follow-up studies in humans have not been reported.

The manner in which the steroid esters evoke their enhanced activity and increased duration of action has puzzled investigators for many years. The classical concept has been that esterification delays the absorption rate of the steroid from the site of injection, thus preventing its rapid destruction. Other factors must be involved, however, since the potency and prolongation of action vary markedly with the nature of the esterifying acid.

The effect of various aliphatic esters of testosterone on rat prostate and seminal vesicles were studied and correlated androgenicity with lipophilicity and rate of ester hydrolysis by liver esterase. The peak androgenic response was observed with the butyrate ester, which was also the most readily hydrolyzed. The more lipophilic valerate ester was slightly less androgenic in a quantitative sense, but its action was longer lasting. It was concluded that the ease of hydrolysis controls the weight of the target organs, whereas lipophilicity was responsible for the duration of androgenic effect. These results explain the low androgenic activity previously noted for hindered trimethylacetate (pivalate) esters, which would be expected to be resistant to *in vivo* hydrolysis.

The effect of etherification on anabolic or androgenic activity has been studied less rigorously. Replacement of the 17β-OH with 17β-OCH_3 markedly reduced androgenic activity but did not greatly affect the ability to counteract cortisone-induced adrenal atrophy in male rats. A series of 17β-acetals, alkyl ethers, and 3-enol ethers, however, showed significant activity when given orally. The cyclohexyl enol ether of 17α-methyltestosterone, for example, was orally 5 times as myotrophic as 17α-methyltestosterone.

Other ethers such as the tetrahydropyranol and trimethylsilyl have oral anabolic and androgenic activity in animals. The

trimethylsilyl ether of testosterone (silandrone) had protracted activity following injection and orally had twice the anabolic and androgenic activities of 17α-methyltestosterone.

5.3.8 Summary of Structure–Activity Relationships

Synthetic modifications of C_{19} steroids have resulted in the enhancement of anabolic activity, even though a pure synthetic anabolic agent that retains no androgenic activity has not been accomplished. Structural changes in two regions of the testosterone molecule have resulted in the greatest enhancement of the anabolic/androgenic ratio. The first region is the C-17 position of the testosterone molecule. Introduction of the 17α-alkyl functionality, such as a 17α-methyl or a 17α-ethyl group, greatly increases the metabolic stability of the anabolic and decreases *in vivo* conversion of the 17β-alcohol to the 17-ketone by 17β-hydroxysteroid dehydrogenases. In addition, esterification of the 17β-alcohol enhances the lipid solubility of the steroids and provides injectable preparations for depot therapy.

The A-ring of testosterone is the second region in which structural modifications can be made to increase anabolic activity. Removal of the C-19 methyl group results in the 19-nortestosterone analogs, which have slightly higher anabolic activity. A major impact on the structure–activity relationships of anabolics can be observed with modifications at the C-2 position. Bioisosteric replacement of the carbon atom at position 2 with an oxygen provides a threefold increase in anabolic activity, as is seen with oxandrolone. Finally, the greatest effects were observed with the addition of heterocyclic rings fused at positions 2 and 3 of the A-ring. The two heterocycles that have lead to the greatest changes are the pyrazole and the isoxazole rings, as seen in stanozolol and androisoxazole, respectively. In these anabolics, the 3-ketone of testosterone is replaced by the bioisosteric 3-imine. Stanozolol, which contains the pyrazole ring at C-2 and C-3, shows the greatest increases when compared to testosterone. Table 9 compares the anabolic activities of nitrogen retention and myotrophic activity for several common anabolics. Figure 10 contains a summary of the structure–activity relationships for anabolic agents.

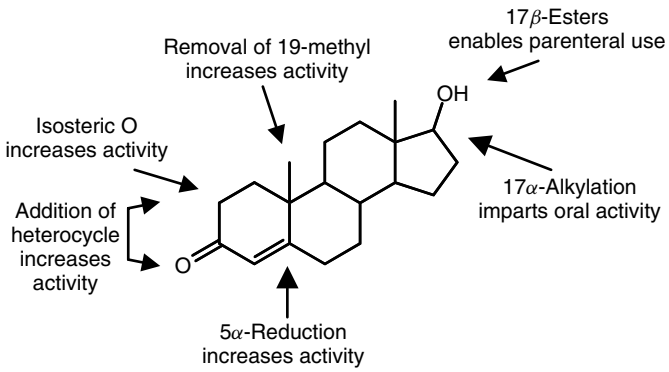


Fig. 10 Summary of structure–activity relationships for anabolic agents

5.4 Absorption, Distribution, and Metabolism

The absorption, distribution, and metabolism of the various anabolic steroids is quite similar to those pharmacokinetic properties of the endogenous and synthetic androgens discussed earlier in the chapter. Again, lipid solubility is critical for the absorption of these agents following oral or parenteral administration. The 17α-methyl group retards the metabolism of the compounds and provides orally active agents. Other anabolics such as methenolone are orally active without a 17α-substituent, indicating that these steroids are poor substrates for 17α-hydroxysteroid dehydrogenase. Reduction of the 4-en-3-one system in synthetic anabolics to give the various α- and β-isomers occurs *in vivo*. The 3-deoxy agent 17α-methyl-5α-androstan-17α-ol was shown to be extensively converted to the 3-keto derivative by liver homogenate preparations. The metabolic fates of stanozolol and danazol have been reported, with the major metabolites being heterocycle-ring opened derivatives and their deaminated products. Finally, both the unchanged anabolics and their metabolites are primarily excreted in the urine as the glucuronide or sulfate conjugates.

5.5 Toxicities

The major side effect of the anabolic steroids is the residual androgenic activity of the molecules. The virilizing actions are undesirable in adult males as well as in females and children. In addition, many anabolic steroids can suppress the release of gonadotropins from the anterior pituitary and lead to lower levels of circulating hormones and potential reproductive problems. Headaches, acne, and elevated blood pressure are common in individuals taking anabolics. The salt and water retention induced by these agents can produce edema.

The most serious toxicities resulting from the use of anabolic steroids are subsequent liver damages. Liver damage including jaundice and cholestasis can occur after use of the 17α-alkylated C_{19} steroids. Also, individuals who have received anabolic agents over an extended period have developed hepatic adenocarcinomas. Such clinical reports serve to underscore the inherent risks associated with anabolic steroid use in amateur athletes for no demonstrable benefits.

6 Androgen Antagonists

A majority of the recent research efforts in the area of androgens has concentrated on the preparation and biological activities of androgen antagonists. An androgen antagonist is defined as a substance that antagonizes the actions of testosterone in various androgen-sensitive target organs and, when administered with an androgen, blocks or diminishes the effectiveness of the androgen at various androgen-sensitive tissues. Androgen antagonists may act to block the action of testosterone at several possible sites. First, such compounds could interfere with the entrance of the androgen into the target cell. A second site of action of androgen antagonists may be to block the conversion of testosterone to its more active metabolite dihydrotestosterone or DHT. Third, competition for the high-affinity binding sites on the androgen receptor molecule may account for antiandrogenic effects. Finally, certain agents such as LHRH agonists can act in the

pituitary to lower gonadotropin secretion via receptor downregulation and thus diminish the production of testosterone by the testis. The substances described in this section act through at least one of these mechanisms.

6.1 Current Drugs on the Market

See Table 10.

6.2 Antiandrogens

6.2.1 Therapeutic Uses

Antiandrogens are agents that compete with endogenous androgens for the hormone binding site on the androgen receptor. These agents have therapeutic potential in the treatment of acne, virilization in women, hyperplasia and neoplasia of the prostate, baldness and male contraception, and clinical studies have demonstrated the potential therapeutic benefits of the antiandrogens. The applications of antiandrogens for the treatment of prostatic carcinoma and for the treatment of BPH have also been investigated. Antiandrogens are effective for the treatment of prostate cancer when combined with androgen ablation, such as surgical (orchiectomy) or medical (LHRH agonist) castration.

6.2.2 Structure–Activity Relationships for Antiandrogens

6.2.2.1 **Steroidal agents.** Several steroidal and nonsteroidal compounds with demonstrated antiandrogenic activity have been utilized clinically. The first compounds used as antiandrogens were the estrogens and progestins. Steroidal estrogens and diethylstilbesterol are used in the treatment of prostatic carcinoma and exert their action via suppression of the release of pituitary gonadotropins. Progestational compounds have also been utilized for antiandrogenic actions with limited success. The inherent hormonal activities of these compounds and the development of more selective antiandrogens have limited the clinical applications of estrogens and progestins as antiandrogens.

A modified progestin that is a potent antiandrogen and has minimal progestational activity is the agent cyproterone acetate (**79**). This compound was originally prepared in search of orally active

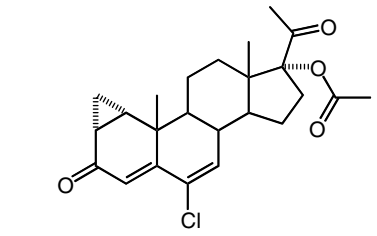
Tab. 10

Generic name (structure)	*Trade name*	*US manufacturer*	*Chemical class*	*Dose*
Antiandrogens				
Flutamide (**91**)	Eulexin	Schering-Plough	Nonsteroidal	Tablets: 125 mg
Bicalutamide (**97**)	Casodex	AstraZeneca	Nonsteroidal	Tablets: 50 mg
Nilutamide (**93**)	Nilandron	Aventis	Nonsteroidal	Tablets: 50 mg 150 mg
Cyproterone acetate (**78**)	Androcur	Schering AG	Pregnane	
5α-Reductase inhibitors				
Finasteride (**104**)	Proscar	Merck	Androstane	Tablets: 5 mg
	Propecia	Merck	Androstane	Tablets: 1 mg

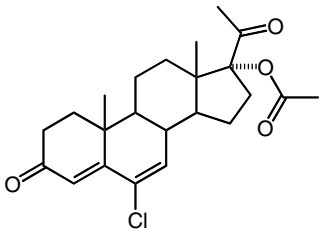
progestins, but was quickly recognized for its ability to suppress gonadotropin release. It was later demonstrated that this compound also bound with high affinity to the androgen receptor and thus competed with DHT for the binding site. Cyproterone acetate has received the most clinical attention in antiandrogen therapy. Cyproterone acetate has produced quite satisfactory results in the treatment of acne, seborrhea, and hirsutism. Therapeutic effectiveness of this agent in the treatment of prostatic carcinoma has been reported. Cyproterone acetate was reported to be a good alternative to estrogens for the treatment of prostate cancer when combined with androgen ablation. However, this combination did not improve disease-free survival or overall survival when compared to castration alone.

Other pregnane compounds that exhibit antiandrogenic actions by binding to the androgen receptor are chlormadinone acetate (**80**), medroxyprogesterone acetate (**81**), medrogesterone (**82**), A-norprogesterone (**83**) and gestonorone capronate (**84**). In addition, medrogesterone exerts antiandrogenic effects by inhibiting 5α-reductase and thus preventing the formation of DHT. Gestonorone capronate interferes with the uptake process in target cells.

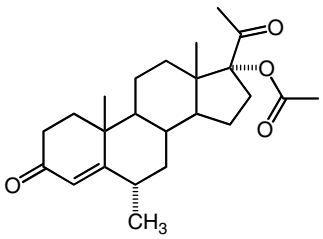
Several androstane derivatives demonstrate antiandrogenic properties. 17α-Methyl-B-nortestosterone (**85**) was prepared and first tested for antihormonal



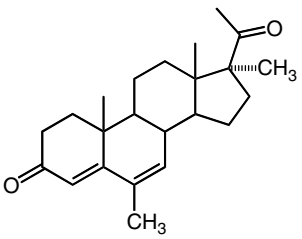
(**79**)



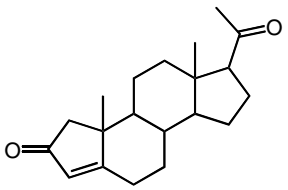
(**80**)



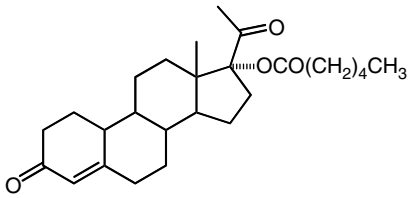
(**81**)



(**82**)



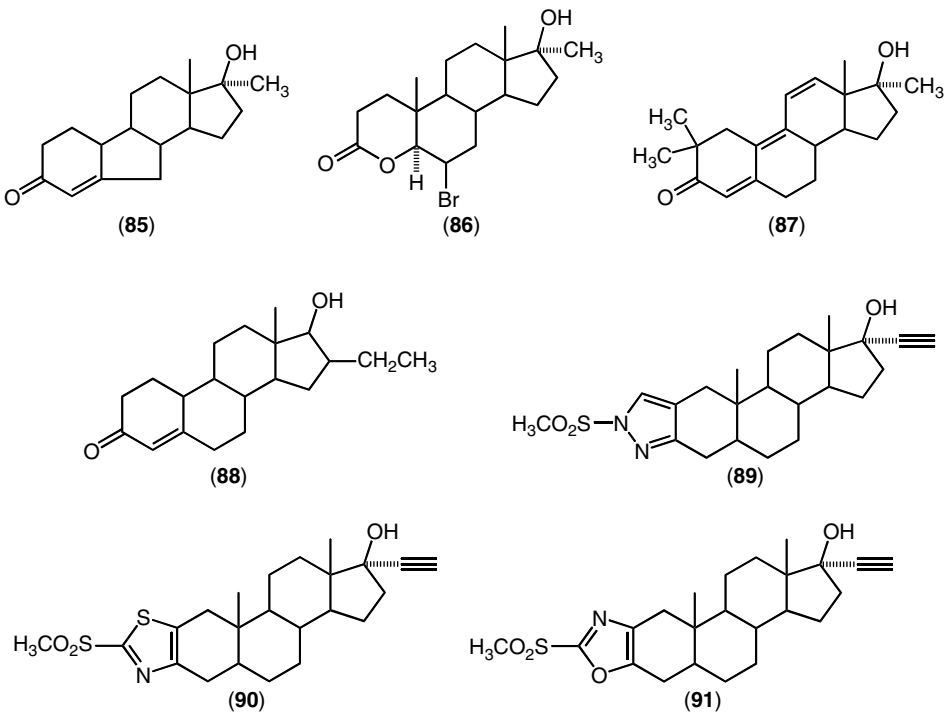
(**83**)

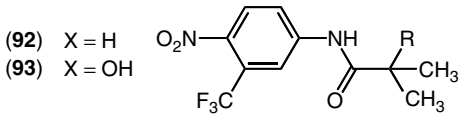


(**84**)

activity. Several other androstane analogs were found to possess antiandrogenic activity, including BOMT (**86**), R2956 (**87**), and oxendolone (**88**). As expected, the mechanism of antiandrogenic action of these synthetic steroids is the competition with androgens for the binding sites on the receptor molecule. Numerous A- and B-ring modified steroids were examined for antiandrogenic activity and the ability to bind to the androgen receptor, demonstrating that the structural requirements of receptor binding site can accommodate some degree of flexibility in the A- and/or B-rings of antiandrogenic molecules. Heterocyclic-substituted A-ring antiandrogens such as zanoterone (WIN 49,596) (**89**) further support these conclusions on the structure-activity relationships of steroidal antiandrogens. Additional A-ring heterocycles identified as novel antiandrogens are the thiazole (**90**) and oxazole (**91**). The optimal substitutions on the A-ring heterocyclic androstanes for *in vivo* antiandrogenic activity are the methylsulfonyl group at the N-1′ position and a 17α-substituent (e.g. 17α-methyl or 17α-ethinyl).

6.2.2.2 **Nonsteroidal agents.** The absolute requirement of a steroidal compound for interaction with the androgen receptor was invalidated when the potent nonsteroidal antiandrogen flutamide (Eulexin, **92**) was introduced. Subsequent receptor studies demonstrated that this compound competed with DHT for the binding sites. The side chain of flutamide allows sufficient flexibility for the molecule to assume a structure similar to an androgen. In addition, a hydroxylated metabolite (**93**) has been identified, which is a more

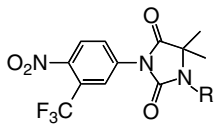




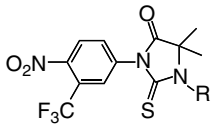
powerful antiandrogen *in vivo*, and has a higher affinity for the receptor than the parent compound. Important factors in the structure–activity relationships of flutamide and analogs are the presence of an electron-deficient aromatic ring and a powerful hydrogen-bond donor group.

Flutamide has been extensively evaluated for the treatment of prostate cancer. Large double-blind studies in prostate cancer patients using a combination of flutamide with an LHRH agonist (as a medical castration) resulted in an increased number of favorable responses and increased overall survival when compared to an LHRH agonist or surgical castration.

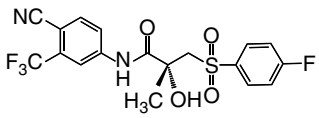
Nilutamide (Anandron, **94**), and related nilutamide analogs (**95**–**97**), and bicalutamide (Casodex, **98**) are other nonsteroidal antiandrogens with a similar electron-deficient aromatic ring and



(**94**) R = H
(**95**) R = $(CH_2)_4OH$



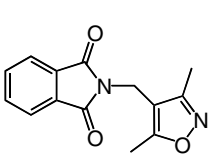
(**96**) R = CH_3
(**97**) R = $(CH_2)_4OH$



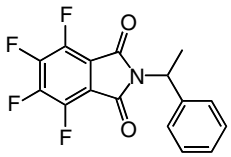
(**98**)

have been shown to interact with the androgen receptor to varying degrees. Nilutamide and bicalutamide are pure antiandrogens and are effective in suppressing testosterone-stimulated cell proliferation. Both nilutamide and bicalutamide have demonstrated effectiveness against prostate cancer.

Other aryl substituted nonsteroidal compounds have also been identified as antiandrogens. DIMP (**99**) is a phthalimide derivative that showed weak affinity for the androgen receptor and poor *in vivo* activity. A series of tetrafluorophthalimides such as (**100**) demonstrated moderate activity as antiandrogens in cell proliferation assays.



DIMP (**99**)



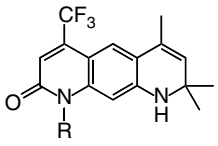
(**100**)

6.2.3 Selective Androgen Receptor Modulators (SARMs)

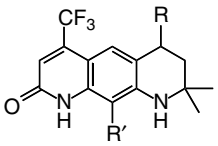
Current research efforts in the medicinal chemistry and pharmacology of androgens and antiandrogens have focused on the development of ligands that produce tissue-selective interactions with the androgen receptor. These ligands, referred to as *selective androgen receptor modulators* (SARMs), may act as antagonists or weak agonists in one tissue but act as strong agonists in another tissue type. Such SARMs would theoretically enable effective treatment of certain disorders affecting bone or muscle with little or no effect on the prostate.

A series of 1,2-dihydropyridono[5,6-*g*]quinolines were identified as novel nonsteroidal antiandrogens on the basis of a cell-based screening approach. Several analogs (**101**–**104**) demonstrated excellent *in vivo* activity, reducing rat ventral prostate weight without affecting serum

gonadotropins and serum testosterone levels.



(**101**) R = H
(**102**) R = CH_3



(**103**) R,R′ = H
(**104**) R,R′ = CH_3

Structural modifications of the antiandrogen bicalutamide have resulted in molecules (**105**–**107**) that produced weak partial agonist activities in the prostate and seminal vesicles (androgen-responsive tissues) and full agonist activity in the levitor ani muscle (anabolic effect) in male rats. Furthermore, these agents did not affect serum gonadotropins and serum testosterone levels, again emphasizing the tissue selectivity for their actions.

6.2.4 Absorption, Distribution, and Metabolism

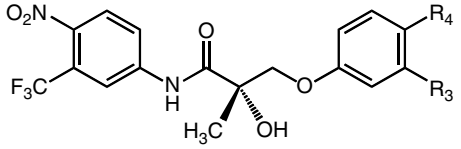
The steroidal antiandrogens exhibit similar pharmacokinetic properties to the androgens and anabolic agents. The lipophilicity of the compounds influences absorption both orally and from injection sites. Reduction of the 3-ketone and 4,5 double bond are common routes of metabolism. An unusual metabolite of cyproterone acetate, 15α-hydroxycyproterone acetate, was isolated and identified in both animals and man. The nonsteroidal antiandrogen flutamide is rapidly absorbed and extensively metabolized *in vivo*. As described earlier, the hydroxy metabolite (**93**) of flutamide is a more potent antiandrogen. The major metabolite of bicalutamide is the sulfone, which has comparable *in vivo* activity. Finally, the antiandrogens are primarily excreted as the glucuronide and sulfate conjugates in the urine.

6.2.5 Toxicities

Side effects of these agents have been identified from various clinical trials. Testicular atrophy and decreased spermatogenesis have been observed during treatment with cyproterone acetate. Certain antiandrogens such as cyproterone and medrogesterone also exhibit inherent progestational activity, suppress corticotropin release, and have some androgenic effects. No hormonal activities were observed for the nonsteroidal antiandrogens, such as flutamide. On the other hand, many nonsteroidal antiandrogens exhibit other endocrine side effects, such as elevated serum gonadotropins and serum testosterone levels. Gynecomastia, nausea, diarrhea, and liver toxicities have been observed in patients on nonsteroidal antiandrogens. Also, resistance to antiandrogen therapy has been observed in prostate cancer patients.

6.3 Enzyme Inhibitors

Enzymes involved in the biosynthesis and metabolism of testosterone are attractive targets for drug design and drug development. Suppression of the synthesis

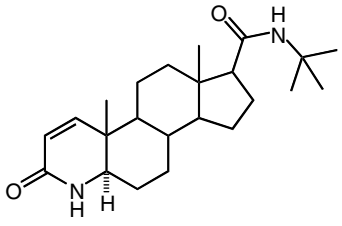


(**105**) R_3 = H, R_4 = F
(**106**) R_3 = H, R_4 = NHC(O)CH_3
(**107**) R_3 = F, R_4 = Cl

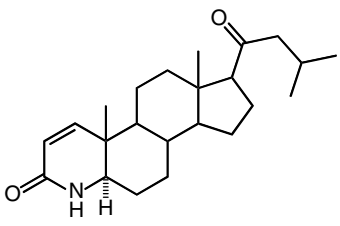
of androgenic hormones and androgen precursors is a viable therapeutic approach for the treatment of various androgen-mediated disease processes and an important endocrine treatment for prostate cancer. Potent inhibition of type 2 5α-reductase in androgen target tissues and the resultant decrease in DHT levels will provide selective interference with androgen action within those target tissues and no alterations of other effects produced by testosterone, other structurally related steroids, and other hormones such as corticoids and progesterone. The cytochrome $P450_{17\alpha}$ enzyme complex displays two enzymatic activities – 17α-hydroxylation to produce 17α-hydroxysteroids and $C_{17}-C_{20}$ bond cleavage (17,20-lyase activity) to produce androgens. In the male, this enzyme is found in both testicular and adrenal tissues, with these organs providing circulating androgens in the blood. Effective inhibition of this microsomal enzyme complex would eliminate both testicular and adrenal androgens and remove the growth stimulus to androgen-dependent prostate carcinoma. Synthetic androgen analogs that inhibit the oxidative metabolism of androgens testosterone and androstenedione to estrogens estradiol and estrone can serve as potential therapeutic agents for controlling estrogen-dependent diseases such as hormone-dependent breast cancer.

6.3.1 5α-Reductase Inhibitors

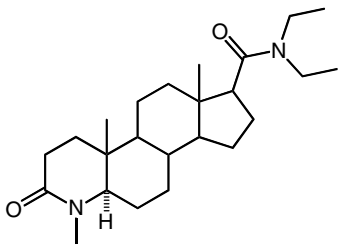
The most extensively studied class of 5α-reductase inhibitors is the 4-azasteroids, which includes the drug finasteride (Proscar, **108**). Finasteride is the first 5α-reductase inhibitor approved in the United States for the treatment of BPH. This drug has approximately a 100-fold greater affinity for type 2 5α-reductase than for the type 1 enzyme, demonstrating an IC_{50} value of 4.2 nM for type 2 5α-reductase. In humans, finasteride decreases prostatic DHT levels by 70 to 90% and reduces prostate size, while testosterone tissue levels increased. Clinical trials demonstrated sustained improvement in BPH disease and reduction in PSA levels. Related analogs (**109–111**)



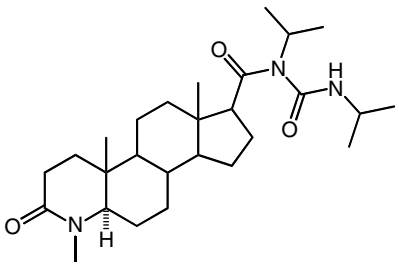
Finasteride (**108**)



(**109**)



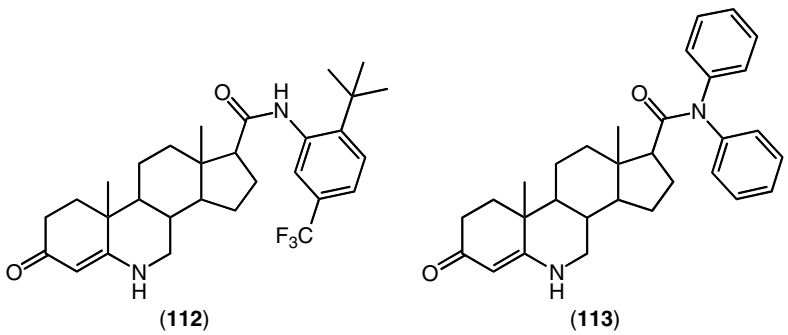
(**110**)



(**111**)

have also demonstrated effectiveness *in vitro* and *in vivo*. These agents were originally designed to mimic the putative 3-enolate intermediate of testosterone and serve as transition-state inhibitors. Subsequently, finasteride was shown to produce time-dependent enzyme inactivation and function as a mechanism-based inactivator. The structure–activity relationships for the 4-azasteroids illustrate the stringent requirements for inhibition of human type 2 5α-reductase. The 5α-reduced azasteroids are preferred, a 1,2-double bond can be tolerated, and the nitrogen can be substituted with only hydrogen or small lipophilic groups. Lipophilic amides or ketones are preferred as substituents at the C-17β position.

Several 6-azasteroids, such as **(112)** and**(113)**, were prepared as extended mimics of the enolate transition state and have also demonstrated potent inhibition of 5α-reductase. The 6-azasteroids are more effective inhibitors of type 2 5α-reductase, but some analogs also exhibit good inhibition of type 2 5α-reductase. Alkylation of the nitrogen can be tolerated; however, a 1,2-double bond decreases inhibitory activity in this series. The best inhibitors contain large lipophilic substituents at the C-17β position. Figure 11 contains a summary



(**112**)

(**113**)

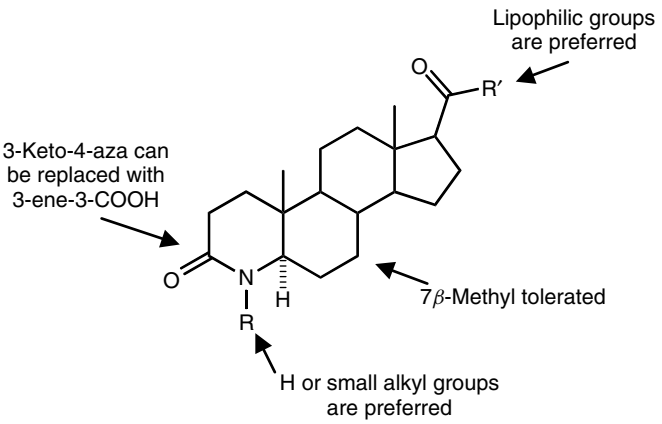


Fig. 11 Summary of structure–activity relationships for 5α-reductase inhibitors.

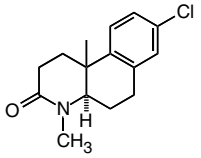
(**120**)

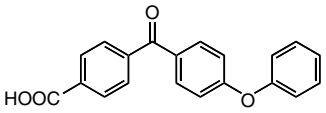
of the structure–activity relationships for steroidal 5α-reductase inhibitors.

Androstadiene 3-carboxylic acids **(114)** and **(115)** were recently designed as transition-state inhibitors and have demonstrated potent uncompetitive inhibition of type 2 5α-reductase. Epristeride (SK&F 105,657, **114**) has demonstrated the ability to lower serum DHT levels by 50% in clinical trials. Other analogs with acidic functionalities at the C-3 position include other androstene carboxylic acids (**116, 117**) and estratriene carboxylic acids (**118**). The allenic secosteroid (**119**) has demonstrated potent irreversible inhibitor of 5α-reductase, even though it was originally developed as an irreversible inhibitor of 3β-hydroxysteroid dehydrogenase/$\Delta^{4,5}$-isomerase. Finally, selective and potent inhibitors of type 1 5α-reductase were developed on the basis of the 4-azacholestane MK-386 (**120**).

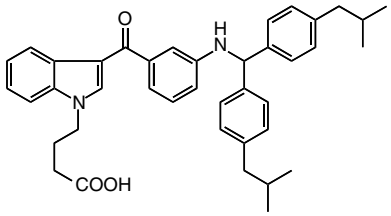
Several nonsteroidal 5α-reductase inhibitors have been developed on the basis of the azasteroid molecule or from high-throughput screening methods. Examples of these nonsteroidal inhibitors include the benzoquinolinone (**121**), an aryl carboxylic acid (**122**), and FK143 (**123**).



(**121**)



(**122**)



FK143 (**123**)

6.3.2 17,20-Lyase Inhibitors

Both nonsteroidal and steroidal agents have been examined as inhibitors of 17α-hydroxylase/17,20-lyase. The nonsteroidal agents studied most extensively are aminoglutethimide (**124**) and ketoconazole (**125**), both *in vitro* and in clinical trials. Objective response rates for treatment of prostate cancer in relapsed patients were observed with high doses of aminoglutethimide and high doses of ketoconazole, but both agents produce frequent side effects. A third nonsteroidal agent that has received extensive preclinical evaluation is the benzimidazole analog, liarozole (**126**), which produced reduction in plasma testosterone and androstenedione levels *in vivo*. Other nonsteroidal agents reported to exhibit 17α-hydroxylase/17,20-lyase inhibitory activity *in vitro* include other imidazole analogs, nicotine, bifluranol analogs, and pyridylacetic acid esters. In general, high doses of nonsteroidal agents are needed to produce significant *in vitro or in vivo* activity. Another potential problem with these agents is nonspecific inhibition of other cytochrome P450 enzymes involved in either steroidogenesis or liver metabolism.

A few studies of steroidal inhibitors of 17α-hydroxylase/17,20-lyase have been reported. An extensive analysis of the specificity of steroid binding to testicular microsomal cytochrome P450 identified several steroids exhibiting binding affinity. One of these, promegestrone (**127**), has been utilized in kinetic analysis of purified cytochrome $P450_{17\alpha}$. An affinity label inhibitor, 17-bromoacetoxyprogesterone (**128**), alkylates a unique cysteine residue on purified cytochrome $P450_{17\alpha}$. Potential mechanism-based inhibitors include 17β-(cyclopropylamino)-5-androsten-3β-ol (**129**) and 17β-vinylprogesterone (**130**). To date, all of these inhibitors exhibit apparent K_i's in the micromolar (μM) range, while the apparent K_m for progesterone is 140 nM. The 17β-aziridinyl analog (**131**) and 17β-pyridyl derivative (**132**) also exhibited similar inhibitory activity.

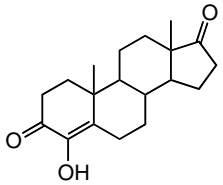
6.3.3 C_{19} Steroids as Aromatase Inhibitors

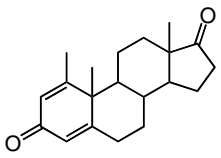
Aromatase is the enzyme complex that catalyzes the conversion of androgens into the estrogens. This enzymatic process is the rate-limiting step in estrogen biosynthesis and converts C_{19} steroids, such as testosterone and androstenedione, into the C_{18} estrogens, estradiol, and estrone, respectively. Inhibition of aromatase has been an attractive approach for examining the roles of estrogen biosynthesis in various physiological or pathological processes. Furthermore, effective aromatase inhibitors can serve as potential therapeutic agents for controlling estrogen-dependent diseases such as hormone-dependent breast cancer. Investigations on the development of aromatase inhibitors began in the 1970s and have expanded greatly in the past two decades.

Steroidal inhibitors that have been developed to date build upon the basic androstenedione nucleus and incorporate chemical substitutents at varying positions on the steroid. These inhibitors bind to the aromatase cytochrome P450 enzyme in the same manner as the substrate androstenedione. Even though the steroidal aromatase inhibitors are C_{19} steroids, these agents exhibit no significant androgenic activity. A limited number of effective inhibitors with substituents on the A-ring have been reported. Several steroidal aromatase inhibitors contain modifications at the C-4 position, with 4-hydroxyandrostenedione (**133**) (4-OHA; formestane) being the prototype agent. Initially, 4-OHA was thought to be a competitive inhibitor, but was later demonstrated to produce enzyme-mediated inactivation. *In vivo*, 4-OHA inhibits reproductive process and causes regression of hormone-dependent mammary rat tumors. 4-OHA is effective in the treatment of advanced breast cancer

in postmenopausal women, and this drug is approved in the United Kingdom for breast cancer therapy. Thus, the spacial requirements of the A-ring for binding of the steroidal inhibitor to aromatase are rather restrictive, permitting only small structural modifications to be made. Incorporation of the polar hydroxyl group at C-4 enhances inhibitory activity. 1-Methyl-1,4-androstadiene-3,17-dione **(134)** is a potent inhibitor of aromatase *in vitro* and *in vivo*; on the other hand, bulky substitutents at the 1α-position are poor inhibitors. At the C-3 position, replacement of the ketone with a methylene provided effective inhibitors.



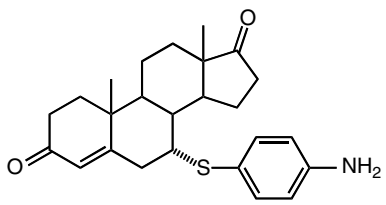
(**133**)



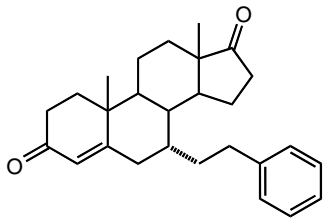
(**134**)

More extensive structural modifications may be made on the B-ring of the steroid nucleus. Bulky substitutions at the C-7 position of the B-ring have provided several very potent aromatase inhibitors. 7α-(4′-Amino)phenylthio-4-androstene-3,17-dione (**135**) (7α-APTA) is a very effective competitive inhibitor, with an apparent K_i of 18 nM. This inhibitor has also demonstrated effectiveness in inhibiting aromatase in cell cultures and in treating hormone-dependent rat mammary tumors. Evaluation of various substituted aromatic analogs of 7α-APTA provided no correlation between the electronic character of the substituents and inhibitory activity. Investigations of various seven-substituted 4,6-androstadiene-3,17-dione derivatives suggest that only those derivatives that can project the 7-aryl substitutent into the 7α pocket are effective inhibitors. More metabolically stable inhibitors were synthesized by replacing the thioether linkage at the 7α-position with a carbon–carbon linkage, such as 7α-phenethylandrost-4-ene-3,17-dione (**136**). Overall, the most effective B-ring modified aromatase inhibitors are those with 7α-aryl derivatives, with several analogs having 2 to 10 times greater affinity for the enzyme than the substrate. These results suggest that additional interactions occur between the phenyl ring at the 7α-position and amino acids at or near the enzymatic site of aromatase, resulting in enhanced affinity.

Numerous modified androstenedione analogs have been developed as effective mechanism-based inhibitors of aromatase. The first compound designed as a mechanism-based inhibitor of aromatase was 10-propargyl-4-estrene-3,17-dione **(137)** (PED; MDL 18,962). MDL 18,962 has an electron-rich alkynyl function on the C-19 carbon atom, the site of aromatase-mediated oxidation of the



(**135**)

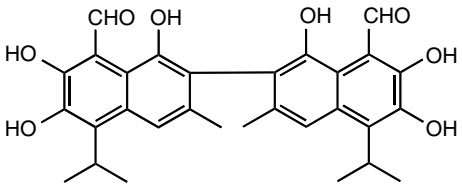


(**136**)

substrate. Although the identity of the reactive intermediate formed is not known, an oxirene and a Michael acceptor have been suggested. This agent is an effective inhibitor *in vitro* and *in vivo*. Other approaches to C-19 substituted mechanism-based inhibitors containing latent chemical groups have provided a limited number of inhibitors. These agents include the difluoromethyl analog **(138)** and a thiol **(139).** Another series of mechanism-based inhibitors have developed from more detailed biochemical investigations of several inhibitors originally thought to be competitive inhibitors. These inhibitors can be grouped into the general categories of 4-substituted androst-4-ene-3,17-diones, such as 4-hydroxyandrostenedione **(133)**, and substituted androsta-1,4-diene-3,17-diones, such as 7α-(4′-amino)-phenylthioandrosta-4,6-diene-3,17-dione (7α-APTADD; **140**), 7α-phen-propylandrosta-1,4-diene-3,17-dione (**141**), and 6-methyleneandrost-4-ene-3,17-dione (exemestane; **142)**. Exemestane (Aromasin) is marketed as second-line therapy for the treatment of breast cancer patients who failed tamoxifen and is effective as first-line therapy in women with advanced breast cancer.

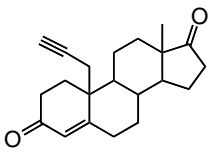
6.3.4 Other Agents

An interesting natural product that lowers circulating androgen levels *in vitro* is the nonsteroidal agent gossypol. Gossypol, (2,2′-binaphthalene)-8,8′-dicarboxaldehyde-1,1′,6,6′,7,7′-hexahydroxy-5,5′-diisopropyl-3,3′-dimethyl **(143)** is a

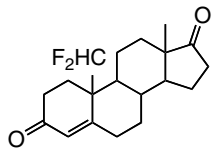


(**143**)

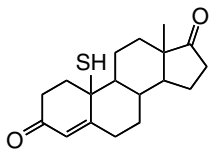
polyphenolic compound contained in the pigment of cottonseed. This natural product has been used in fertile men in China as an effective male contraceptive agent for many years; its antifertility effects on reproductive endocrine tissues are observed at 1000-fold lower doses than its toxic effects in other tissues. Gossypol has been shown to disrupt spermatogenesis by inhibiting lactate dehydrogenase-X (LDH-X), to interfere with steroidogenesis in testicular Leydig cells, and to hinder the function of primary cultures of Leydig and Sertoli



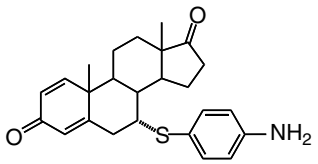
(**137**)



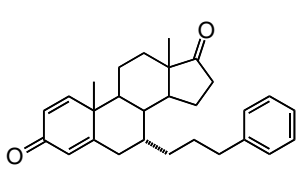
(**138**)



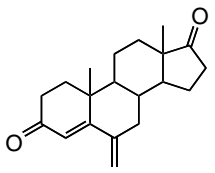
(**139**)



(**140**)



(**141**)



(**142**)

cells. In addition, gossypol is also capable of altering steroid biosynthesis in the female reproductive systems. The antisteroidogenic effect of gossypol in cultured bovine luteal cells involves suppression of the activities of adenylate cyclase and 3β-hydroxysteroid dehydrogenase (3β-HSD). Reproductive endocrine tissues are also sensitive to metabolites of gossypol, such as gossypolone. Gossypolone, a major metabolite formed by gossypol oxidation, inhibits both 3β-HSD and cytochrome P450scc activities in cultured bovine luteal cells and suppresses adrenocorticotropic hormone-induced corticosterone secretion in cultured rat adrenocortical cells at a similar potency as gossypol. Gossypol metabolites have also demonstrated inhibitory action on hCG-induced testosterone production in young male rats. The major side effects of gossypol therapy fatigue, gastrointestinal upset, weakness, and hypokalemia thus limit its therapeutic usefulness.

7 Summary

The steroid testosterone is the major circulating sex hormone of the male and serves as the prototype for the androgens, the anabolic agents, and androgen antagonists. The endogenous androgens are biosynthesized from cholesterol in various tissues in the body; the majority of the circulating androgens are made in the testes under the stimulation of the gonadotropin LH. A critical aspect of testosterone and its biochemistry is that this steroid is converted in various cells to other active steroidal agents. The reduction of testosterone to dihydrotestosterone is necessary for the androgenic actions of testosterone in androgen target tissues such as the prostate. On the other hand, oxidation of testosterone by the enzyme aromatase to yield the estrogens is crucial for certain CNS actions. Investigations of these enzymatic conversions of circulating testosterone continue to be a fruitful area of biochemical research on the roles of the steroid hormones in the body. Additionally, the elucidation of the mechanism of action of the androgens in various target tissues receives ongoing emphasis. The androgenic actions of testosterone are due to the binding of DHT to its nuclear receptor, followed by dimerization of the receptor complex and binding to a specific DNA sequence. This binding of the homodimer to the androgen response element leads to gene expression, stimulation of the synthesis of new mRNA, and subsequent protein biosynthesis. Other actions of testosterone, particularly the anabolic actions, appeared to be mediated through a similar nuclear receptor-mediated mechanism. Many of the intricate biochemical events that occur during the action of the androgens in their target cells remain for further clarification. Nevertheless, receptor studies of new agents are an important biological tool in the evaluation of the compounds for later, in-depth pharmacological testing.

The synthetic androgens and anabolics were prepared to impart oral activity to the androgen molecule, to separate the androgenic effects of testosterone from its anabolic effects and to improve upon its biological activities. These research efforts have provided several effective drug preparations for the treatment of various androgen-deficient diseases, for the therapy of diseases characterized by muscle wasting and protein catabolism, for postoperative adjuvant therapy, and for the treatment of certain hormone-dependent cancers. The synthetic anabolics have also resulted in the abuse of these agents in

athletics. Finally, the most recent area of research emphasis is the development of the androgen antagonists, both steroidal and nonsteroidal agents. The two major categories of these antagonists are the antiandrogens, which block interactions of androgens with the androgen receptor, and the inhibitors of androgen biosynthesis and metabolism. Such compounds have therapeutic potential in the treatment of acne, virilization in women, hyperplasia and neoplasia of the prostate, and baldness and for male contraception. The current focus on the development of SARMs enables tissue-selective activation of the androgen receptor, such that these ligands may act as strong agonists in one tissue while being antagonists or weak agonists in another tissue type. A number of androstane derivatives are also being developed as inhibitors of aromatase for the treatment of hormone-dependent breast cancer. Thus, the numerous biological effects of the male sex hormones testosterone and dihydrotestosterone and the varied chemical modifications of the androstane molecule have resulted in the development of effective medicinal agents for the treatment of androgen-related diseases.

Keywords

Large-insert Clones
Clones made as cosmids, fosmids, BACs or YACs, with an insert size around or over 40 Kb.

Minimal-tiling-path Clones
Physically mapped clones that cover their source DNA molecule with a single path and least amount of overlaps.

Physical Gap
Gaps not covered by available clones in a clone assembly.

Physical Map
DNA sequences or chromosome segments delineated by a set of ordered and oriented markers or fingerprinted clones.

Scaffold
A group of ordered and oriented contigs with physical contiguity but without sequence contiguity.

Sequence Contig
A contiguous sequence assembly composed of overlapping sequences.

Sequence Gap
Gaps not covered by sequences in a sequence assembly.

Shotgun Sequencing
A DNA sequencing technique used for achieving sequence contiguity by acquiring random sequences from clone libraries made of the target DNA.

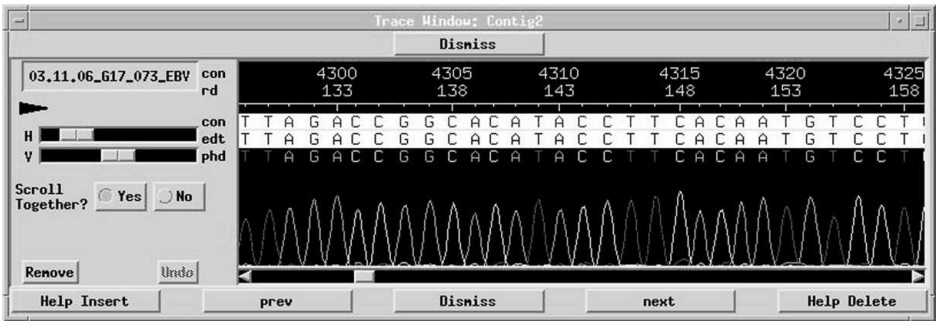
Shotgun sequencing (SGS) is primarily a large-scale sequencing (LSS) technique that does not rely on precise guiding information about the target DNA, which includes large-insert clones and single genomes, ranging from thousands of basepairs (Kb) to billions of basepairs. A mixture of smaller genomes can also be sequenced in a similar way when retrospective means are available to assemble and distinguish them. It provides a fast and cost-effective way of sequencing large genomes regardless of whether the project as a whole takes a ''whole-genome'' (WG) or ''clone-by-clone'' (CBC) approach. The success of SGS essentially depends on random sampling, high-quality data, sufficient sequence coverage, effective assembly, and gap closing procedures. SGS has already demonstrated its tremendous power in sequencing not only microbial genomes but also large eukaryotic genomes, such as those of the cultivated rice and the laboratory mouse. Together with improved sequencing technologies and computing tools, SGS is expected to play a central role in the field of genomics, especially when the latter has to constantly face some major challenges, scientific, managerial, and political. Some of the scientific challenges relate to the effective sequencing of large, polyploid, and mixed genomes, as well as those with highly repetitive sequence contents. A key managerial challenge is for the operators to consistently produce high-quality data while increasing throughput and reducing cost. It is always a tough decision for a steering committee organizing a genome project to choose between WG and CBC, but SGS is always the basic technique of choice.

1 Introduction

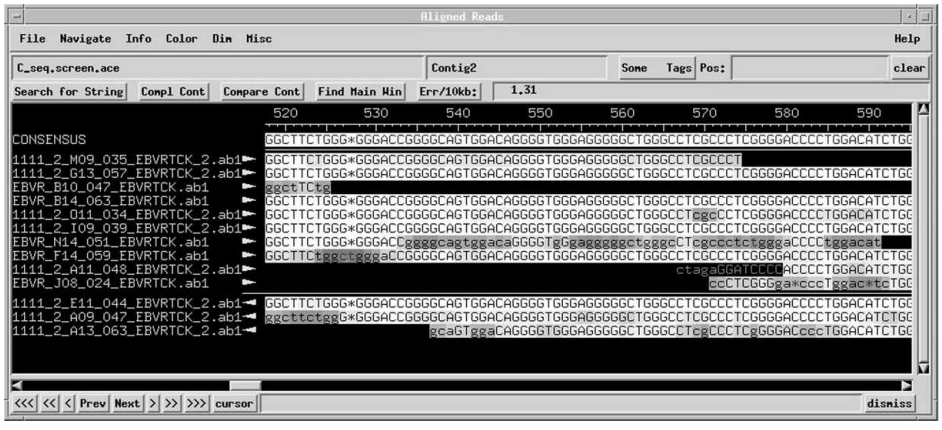
DNA sequencing has become one of the essential laboratory methods used in molecular biology, together with DNA cloning, DNA microarray, polymerase chain reaction (PCR), electrophoresis, chromatography, and centrifugation. It has become not only a fundamental method of determining genome sequences but also a basic tool for identifying DNA methylation sites and sequence polymorphisms. In both scale and scope, DNA

sequencing outperforms all other molecular technologies in acquisition of basic genomic information, thereby paving the way for other genome-scale, technology-oriented disciplines and, to use contemporary terminology, the numerous ''-omics'' (transcriptomics and proteomics being well-accepted examples) that will be leading biologists into the future decades, providing new data, ample information, fresh knowledge, and innovative insights.

At the leading edge of genomics, the principal ideas of DNA sequencing are not fundamentally different from the technical innovations demonstrated in the early days of technology development in molecular biology. When a cloned DNA molecule is larger than one (from one end) or two (from both ends) sequencing readouts (often referred as *sequencing reads*; screenshots of a sequence trace and a sequence alignment are shown in Fig. 1) from an electrophoresis-based instrument, its full-length sequence has to be obtained in one of the following two ways: (1) a stepwise primer-directed ''walking'' strategy, based



(a)



(b)

Fig. 1 Screenshots of a partial sequence read (a) and a sequence assembly with aligned sequences (b). Brightness in (b) indicates the quality of the sequence as estimated and displayed by a software tool kit (sequence assembler), Phrad-Phrep-Consed.

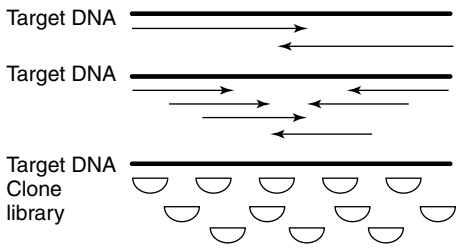


Fig. 2 Two basic ways of sequencing DNA beyond a size of two sequencing reads: (a) to ''walk'' in a stepwise way from both ends by designing primers based on newly acquired sequence information from a previous walk, and (b) to ''shotgun'' the target DNA into smaller pieces that are carried by a clone library (or subclones). Random sequencing of the subclones with high redundancy leads to an assembly whose consensus sequence is equivalent to that of the target. Arrows depict sequencing reads and their directions.

on newly acquired sequences; (2) a parallel subcloning strategy, based on directed or ''shotgun'' cloning techniques by breaking the target DNA into smaller pieces so that a collection of sequencing reads from overlapping ''subclones'' sufficiently covers the entire target length (Fig. 2). It is obvious that the choice of approaches depends on the capability and throughput of a sequencing operation. Whereas one is managed serially and is therefore limited in scale, the other involves paralleling and is suitable for high-throughput, large-scale operations. The current capability of a typical sequencing instrument limits the sequencing length in a single run to just 500 to 2000 basepairs (bp). Besides solutions involving instrumentation (such as parallelization and incremental increase of read length), the choice of approaches for any large-scale sequencing (LSS) project has to take advantage of SGS for large-insert clones over tens of kilobasepairs (Kb), or genomes in a size range from a few kilobases (such as large viral genomes) to a few megabasepairs (Mb; such as bacterial genomes), right up to a few hundred or even a few thousand Mb in length (such as higher plants and animals).

SGS has been successfully applied for sequencing many large genomes, essentially at two levels, targeting either clones or whole genomes. Large genome-sequencing projects are often initiated by large-insert clone-based physical mapping, especially for important model organisms from representative taxonomic groups; the Human Genome Project (HGP) is the most famous example. These physical mapping techniques include YAC (yeast artificial chromosome)-based or BAC (bacterium artificial chromosome)-based STS (sequence-tagged site) mapping, and restriction-digest mapping with different types of large-insert clones. These clones are subsequently sequenced by SGS, guided by a collection of clones that cover the targeted region with least overlaps, often termed as minimal tiling path (MTP). Physical maps providing anchored clones for sequencing are often referred to as *sequence-ready maps*. In a map-directed process, sequence data are captured at clone level and merged, after data from overlapping clones are completed individually. Although SGS is utilized at clone level, such an approach is often referred as a *clone-by-clone SGS or CBC-SGS*, as opposed to a whole-genome SGS, or WG-SGS. In the second scenario, when sufficient information (including estimated genome size, number of chromosomes, GC-content, repeat contents, and genetic homogeneity) about a genome has been acquired either from the organism itself or from a closely related

one, the WG-SGS approach becomes feasible, and is often the method of choice. In most cases, SGS has its ''sweet range'' in sequencing genomes, from a few Mb to a few hundred Mb. However, the quality and completeness of a final assembly habitually depends on repetitive sequence content, clonability, and complexity of the genome, coupled with other factors such as funding, project management, and homogeneity of the source DNA (sequence variations among individuals that donate DNA sometimes are known to delay a quality sequence assembly for months or even years). Before long, SGS will have to face even greater challenges, when it begins to be applied to genomes in a size range around thousands of Mb, polyploid genomes, and even a mixture of genomes. Novel approaches, techniques, and computing tools will have to be gradually introduced in order to make SGS a more efficient and robust technique. Two major significant factors are driving this effort:: the ever-increasing desire for more and more sequence information, and the incremental cost reductions, as evidenced in the history of genomics over the past decade.

1.1 A Brief History of DNA Sequencing

The concept and technology of DNA sequencing have been evolving over the past thirty years. The initial phase of DNA sequencing was born with the development of the *basic technology*, fundamentally a series of technology advancements in DNA sequencing and molecular cloning around the early 1970s. The second phase began with the proposals to set up the Human Genome Project in 1983 and 1984. The decade following this, before the advent of LSS of HGP in 1995, was the most critical period for *special technology and concept* development, most notably physical mapping and DNA sequencing. The past 10 years have been the *Large-scale Sequencing Era*, which is undoubtedly going to last at least another decade or even longer. In this period, alongside additional technological and strategic improvements, there has been a collective effort on the part of those involved in sponsored academic research as well as those belonging to the profit-making biotech industry, to make improvements in the areas of policy development, organizational reforms, and management practices. This has resulted in a continual reduction in the cost of sequencing from the earlier standard level of ''$1 per base'' (calculated as $40 per sequence read on the assumption of 8x coverage of a target genome) when HGP first started, to the real cost of $15 per read when HGP transitioned into the Large-scale Sequencing Era, to a current cost estimate of $1 per read. These are the estimated direct costs for academic operations and not the retail price offered by private companies. Some academic institutions have claimed lower costs in a rather variable range from $0.3 to $0.8. The cost of sequencing is expected to go down continually over the next 5 to 10 years, dropping at a rate of 50 percent every two years (Fig. 3). Meanwhile, of course, some new ground-breaking technology could emerge and dramatically change the current practice.

The DNA polymerase-based sequencing method and a variety of molecular cloning techniques are the centerpieces of contemporary DNA sequencing technology. In the early days, primer-dependent tactics and shotgun principles were already being employed in tackling large pieces of DNA molecules and certain levels of

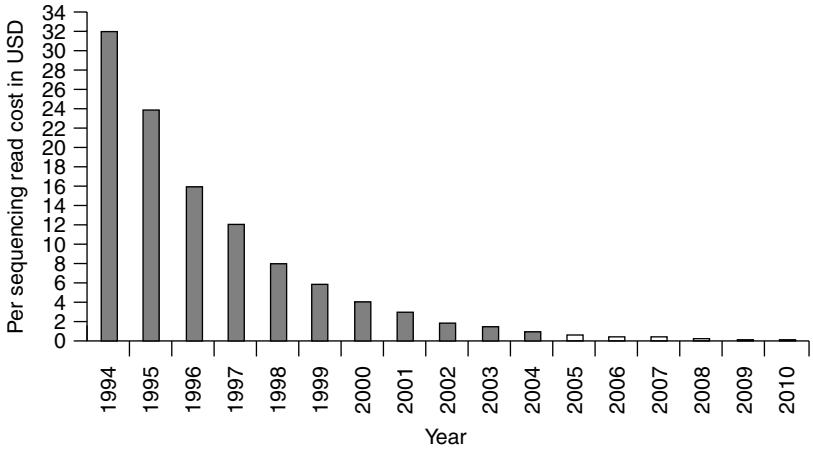

Fig. 3 The trend of estimated cost reductions since the beginning of large-scale sequencing (LSS). Although the legendary estimate, ''one dollar per basepair,'' at the beginning of the HGP should be marked as a starting point, LSS was not launched on a full scale until the middle of 1990s when capillary sequencers and robotics-aided basic sequencing protocols became available. Real academic costs are calculated over a course of 10 years (1995–2004; solid bars). The costs beyond 2004 are estimated according to the trend (open bars). An empirical rule becomes clear, namely, that the sequencing cost is halved every two years.

complexity, such as overhang sequences that are common in bacteriophages. It should be remembered that it took the pioneers over a couple of decades to achieve an increase in sequencing read length from a few tens of basepairs to a couple of hundred basepairs. The first genome sequenced by a ''shotgun'' design was the bacteriophage phiX174 (5386 bp in length and containing 10 genes) published in 1977. Since then, bacterial cloning systems have leveraged the biology of both bacteriophages and plasmids. They have been designed to achieve higher yields for cloned DNA (such as high-copy plasmid), and equipped with polylinkers composed of multiple cutting sites of commonly used restriction enzymes, as well as several choices in the matter of antibiotic resistance.

The WG-SGS approach was first successfully applied to a microbial genome, *H. influenzae* (1 830 138 bp in size; a bacterium causing upper respiratory infection) in 1995. The success of the WG-SGS approach has opened the floodgates for microbial genome sequencing. As a result, collections of completed microbial genome sequences are updated almost on a daily basis, now number in the hundreds. The first metazoan genome to be sequenced using the WG-SGS method was the *Drosophila* genome with a euchromatic content of slightly over 122 Mb. The SGS data were subsequently combined with those from the public sequencing effort on the same organism, thereby unlocking another information gateway towards insect genomics. Insect genomes, such as mosquitoes and silkworms, were sequenced subsequently by the WG-SGS method in different institutions. The Human Genome Project was carefully planned and initiated with a genome-scale

physical mapping effort, followed by SGS of large-insert clones, including YACs and cosmids, but mostly BACs. It was therefore labeled as an SGS approach, although the large-insert clones were sequenced one by one using SGS. The landmarks for CBC-SGS were *E. coli* K-12 (the first bacterium), *S. cerevisiae* (the first eukaryotic species), and *C. elegans* (the first metazoan species). Private teams later used the WG-SGS approach to interrogate the human and mouse genomes, but the wealth of public data were also carefully merged to arrive at the final assemblies. The mouse genome was the first trial of the WG-SGS strategy by the publicly supported consortium and the rat genome was the next. Following the *Arabidopsis* genome (150 Mb), the first plant genome deciphered with a CBC-SGS approach, the first crop plant genome – the rice genome (450 Mb) – has been sequenced four times. Two of the efforts were led by private companies with the WG-SGS approach. An international consortium took a CBC approach and has completed sequencing several chromosomes of the rice genome from the same cultivar as the one sequenced by the private companies, namely, a *japonica* rice, *Nipponbare*. The fourth rice genome, an *indica* variety, was sequenced by our own institute as part of its Hybrid Rice Genome Project using WG-SGS strategies. The WG-SGS wave has reached new heights. Large genomes of various species, even certain taxonomic groups (such as a suite of vertebrates, mammals, and grasses), are being placed in undergoing sequencing operations, and these are expected to be completed in the next 5 to 10 years. The selection of these targets for sequencing is justified because of their relevance to human biology and diseases, as well as to broader areas of economic interest such as domestic crops, farm animals, and their wild relatives.

From a technical perspective, two major breakthroughs have revolutionized large-scale sequencing. The first is the invention of large-insert clones, YAC being the first and BAC, the second. They offered unprecedented substrates for both LSS and physical mapping. The timely invention of PCR technology also stimulated the new physical mapping concept of STS. Since mapped YACs have to be subcloned into bacterial vectors for sequencing (because YACs are intermingled with host chromosomes, their DNAs are not readily separable by straightforward chemical methods), BACs have now become the preferred substrate. The second breakthrough was the invention of four-colorfluorescence-based methodology and instrumentation, allowing for a high degree of parallelization and miniaturization to come into play. Capillary-based sequencers are the current choice of high-throughput sequencing, although versions of slab-gel-based sequencers emerge from time to time. A central computational support for large-scale sequence acquisition and analysis is the concept of a quality score system for each sequenced base, pioneered by Phil Green and his colleagues. Other emerging technologies such as ''single molecule'' sequencing technology are being sponsored by certain funding agencies, but these are still in their infancy or at a proof-of-principle stage, and may take years of development and research in order to be introduced to a sequencing equipment assemblage.

On the whole, it is clear that SGS has becoming a mainstay of LSS because of collective experience, sharpened software tools, and increasing knowledge about the structure of target genomes. It is most

likely that many large genomes will be sequenced by the SGS method rather than by the CBC one in the years to come.

1.2 Overview of SGS Methodology and Application

Other than biological significance, two categories of practical issues have to be considered for any large genome project beyond a few Mb in target size: managerial and technical. In general, whereas the total number of sequence reads required to cover a genome length is comparable in the two versions of SGS, namely, WG and CBC, WG-SGS is both money- and time-saving because it largely skips a labor-consuming step: clone library construction based on sequence-ready maps. For a CBC-SGS approach, each of the large-insert clones (often BACs) has to be shotgun cloned into small-insert clones (often plasmids). The larger the genome (or the more the MTP clones), the more the libraries that have to be constructed. For instance, to sequence a 500-Mb genome, over 3500 physically ordered BAC (assuming 150 Kb as an average length for BACs) clones have to be made into subclone libraries, whereas only a few carefully prepared small-insert clone libraries are adequate for WG-SGS. If carefully planned, a genome project could start with randomly picked BACs from a whole-genome library that sufficiently covers an entire length, followed by a low-pass sequence sampling (such as a few hundred sequence reads) and sequence overlap assessment, and finished with parallel procedures to complete each BAC of MTP. Although such a strategy appears feasible, it is as yet untried. It is composed of multiple tasks at different levels, for which the project has to be managed in a serial fashion. In contrast WG-SGS, in its unique path, provides a highly parallel process avoiding managerial pressures often created at intermediate levels. Table 1 lists some completed genome sequences in categories of sequence methods, WG-SGS and CBC-SGS.

SGS has never been a stand-alone technology. It includes many other cloning and computing techniques and strategic approaches along the path of its expanding applications. The first set of technologies has to do with molecular cloning. Currently, the preferred cloning systems are BACs, that are best for cloning large DNA fragments and for clone stability; and plasmids, best as regards high yield and readiness for preparing DNA templates for sequencing. BACs are also easier to fingerprint by six-base cutting enzymes (as opposed to YACs), and the system has a copy number control scheme that is believed to enhance clone stability in bacterial hosts, as compared to cosmids. Other merits of using BACs include their simple, robust DNA preparation procedures for parallel and scaled operations, and the fact that they are better reagents for physical mapping for long-range coverage and contiguity (BACs can be made in an insert size range of 100 to 200 Kb) than the lambda packaging-based cosmids and fosmids, which are limited by an insert size range of 30 to 40 Kb. However, one has to realize that cosmids and fosmids are both suitable for SGS on a limited scale and BAC libraries are not as easy to make in large quantity as the cosmid system. Regardless of which of the large-insert cloning systems is employed, plasmids provide an excellent direct substrate for SGS sequencing, whereas others can only be directly end-sequenced on a limited scale for achieving better contiguity over a variable range. On certain occasions, miniature BACs, or mini-BACs

Tab. 1 Representative sequenced genomes with WG-SGS and CBC-SGS strategies.

Note: Some of the genomes have not yet been completed, such as *B. mori, R. norvegicus, C. briggsae* and *M. musculus.*

(10 to 20 Kb) are used to compensate some of the systemic drawbacks when insert size and clone stability are of major considerations. Occasionally, mini-insert (100 to 200 bp) clones and YAC clones have to be utilized in coping with low GC-content DNA that is extremely unstable in bacterial hosts, such as is the case in the sequencing of the malaria parasite, *P. falciparum*.

The second set of technologies crucial for SGS comprises various DNA preparation methods for sequencing substrates. Two basic criteria for choosing a practical method are scalability and cost; both demand robust and automatable protocols. The M13 bacteriophage system used in the early days of LSS was soon given up, largely because of its requirement for repeated precipitation steps in isolating phage particles and DNA, which significantly hinders the automation process, although it is capable of producing high-quality data. Being part of the rate-limiting steps in large-scale sequencing, plasmid DNA preparation methods have evolved a great deal over the past few years. Besides alkaline lysis protocols, absorbent-based and isothermal amplification protocols are

also widely used in plasmid DNA preparations. In the absorbent-based protocol, centrifugation steps are mostly reduced to simple pluming, and the isothermal amplification protocol is aimed at eliminating bacterial precipitation and plasmid DNA preparation all together. PCR-based protocols also seem to be convenient in meeting the need for preparation of sequencing templates, but we have yet to see a robust one that yields high-quality data. Despite the difficulty in applying PCR technology to template preparations for large-scale SGS, it is still used in all sequencing reactions, catalyzed by a thermal stable polymerase. It is also vital in primer-directed walking and PCR product sequencing for joining sequence contigs in the finishing phase of genome-sequencing projects.

The most demanding component of all SGS-related technologies is biocomputing, broadly termed as bioinformatics, especially for WG-SGS. Bioinformatic tools are often packaged when applied to almost all aspects of SGS, such as data management, sequence contig assembly, and genome annotation. While being less selective concerning databases and data management systems, SGS relies heavily on sequence assembly and gene-finding algorithms. A WG-SGS project can be initiated only when a qualified sequence assembler is put in place. There are several versions of sequence assembly software packages that are able to handle a target size range of a few tens of Kb to a few Mb (Table 2). By far, the most popular package is the Phred-Phrap-Consed developed by Phil Green and his colleagues. For large genomes in a size range of a few tens of Mb to hundreds of Mb, even thousands of Mb, additional algorithms are required to facilitate the complicated assembly process, including repeat identification and masking, contig and scaffold assembly, and customized annotation. Finally, in most of the cases, a specialized database has to be built to host the integrated information for a sequenced genome, in order to better serve the relevant research community in addition to timely submissions of the generated data to the public databases across continents.

Even though most of the genome projects are aimed at producing a ''fully finished'' genome sequence (the expected end-product for representative or important genomes), WG-SGS is also capable of producing three intermediate products: a genome survey sequence, targeted genome sequences, and a working draft

of the whole genome. Each serves a special purpose and is vital for predicting the outcomes of a project in many circumstances. For instance, the genome survey sequence that covers less than 1x of the genome could provide information about the repeat contents and gene structures. It can also help in gathering polymorphisms when DNA sources from several closely related breeds are compared with a complete or nearly complete reference genome. A noteworthy example is the chicken polymorphism study where DNA sequences from three major domesticated breeds with nearly 1x coverage collectively are able to offer over three million SNPs (single nucleotide polymorphisms). One apparent application for targeted genome sequences is that the sequencing reads from an ongoing project can provide markers for identifying large-insert clones for the target regions before pictures of a genome or a locus become clear. A genome working draft (about 6x coverage of a genome) is the most popular product of many genome projects. It often covers 95 to 99% of the functional content of a genome and also anchors genes and their regulatory regions physically on the chromosomes when physical and genetic maps of the organism become available. Since finishing a genome sequence to a reasonable contiguity is difficult and expensive, sometimes impossible, not all genomes are expected to be finished. In fact, in many cases a finishing standard is debatable and occasionally highly controversial. Therefore, genome working draft sequences of many large eukaryotic organisms are expected to stay as such for a long time, though the community standard for finished prokaryotic genomes remains a gap-free sequence.

When zeroing in on the structural dynamics of large eukaryotic genomes, one will soon realize that there are numerous differences among genomes of taxonomically distant species to be considered before a genome-sequencing project is proposed. The most notable differences are between animal and plant genomes. Among animal genomes, genes spread over almost the entire length of a genome and transposable elements are inserted into introns, enlarging the genes over the evolutionary timescale. Most of the animal genes have more than a few alternatively spliced variants. The conjecture is that animal RNA splicing (spliceosomal) machinery is better established and complex enough to be capable of handling large introns ranging from a few tens of Kb to hundreds of Kb. Plant genomes are different from animal genomes in these same two areas. First, plant genes remain small in size owing to slower growth of the intron size, and transposable elements are mostly inserted into intergenic spaces. Transposable elements jump onto each other, forming gene-free clusters in high densities between gene ''islands.'' As plant genomes evolve, only repetitive contents grow thus enlarging repeat clusters and not the gene islands. This is the case with wheat (1700 Mb) and corn (1200 Mb) as opposed to rice, which has a 500-Mb genome, nearly half of it as repeats of different kinds. Second, alternative splicing among plant genes is not as prevalent as it is among animal genes, perhaps as a result of less capable splicing machineries. Figure 4 illustrates the different genome structural models.

There are some minor issues relating to insect genomes wherein the heterochromatic contents are high. Insect genomes in sizes of hundreds of Mb seem not much different from other animal genomes of different taxonomic groups, but the basic organization of larger ones in the order of thousands of Mb are unknown so far.

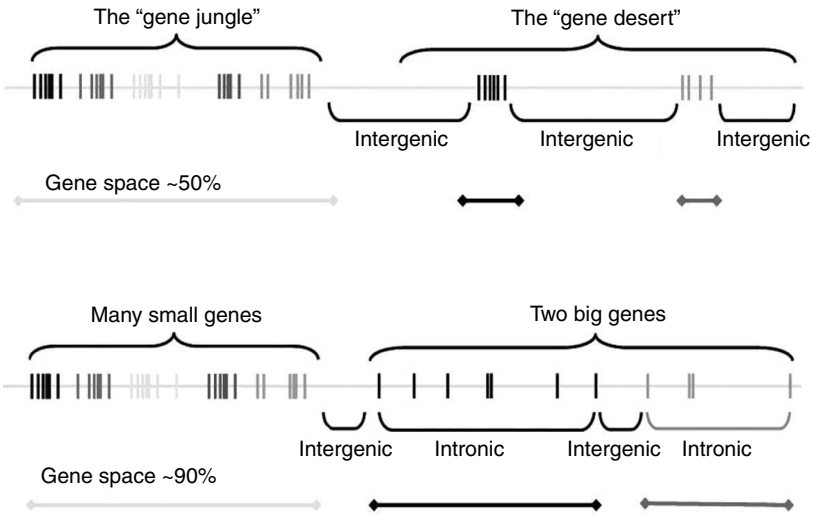

Fig. 4 A schematic illustration explaining major differences in basic genome structures between animals (represented by human) and plants (represented by rice). Genes are depicted as vertical bars in different shades. Gene spaces (diamond-headed lines) are estimates based on real experimental data. Spaces (horizontal brackets) between and within genes are defined as intergenic and intronic sequences, respectively. ''Gene jungles'' and ''gene deserts'' exist in plant genomes but are not known in animal genomes. In animal genomes, most of the chromosomal spaces are occupied by genes at different densities. Gene-poor regions most probably contain large genes or large introns.

Protists have the most diverged genomes studied to date and their genome sizes vary from a few tens of Mb to a few thousand Mb (Fig. 5). The GC-content of these organisms varies dramatically; the most extreme case was found in the malaria parasite, *P. falciparum*, which has a GC-content of 18%. As more genomes of these primitive but unusual organisms are sequenced, we will know better about their genome organizations.

2 Essentials for SGS

Regardless of whether it is associated with WG or CBC, SGS has five irreducible steps (Fig. 6): clone library construction, clone sequencing, sequence assembly, sequence annotation, and data analysis. The rest are either managerial (such as data handling, integration, and release) or political (such as cost accounting and choice of strategies) issues. The first two steps are apparently ''wet-bench'' related (other than data and database management) and the others are mostly bioinformatics, except a hidden ''time bomb'' in sequence assembly – sequence finishing, where close coordination between the two seemingly distinct disciplines is of the essence for completing a project successfully. The wet-bench operators must make sure that there are no obvious technical flaws in the raw data and that the assembled sequence is in agreement with preexisting data and knowledge, and the bioinformatics

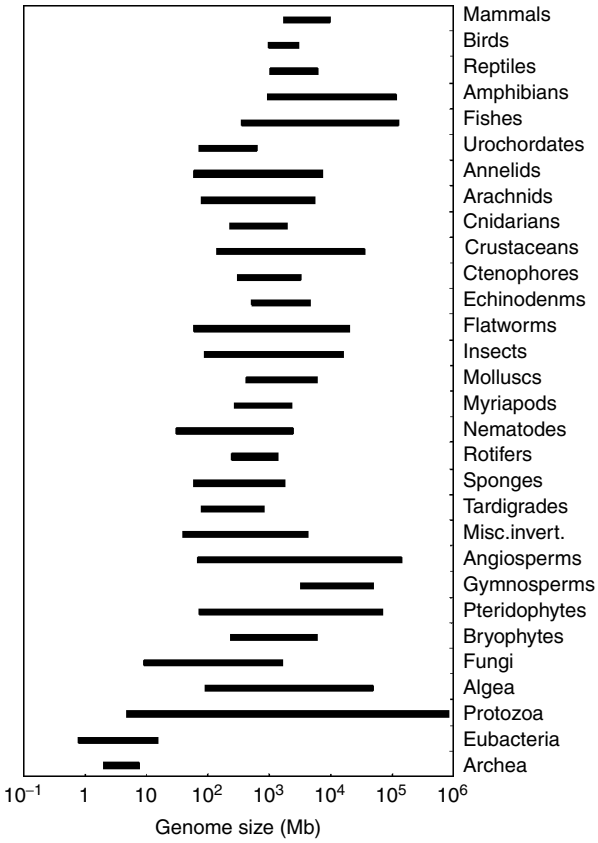

Fig. 5 Genome size distribution from organisms of selected taxonomic groups. The genome size is converted to nucleotide lengths from c-values. Horizontal bars mark the range of genome sizes for a given group. Polyploidy is not factored in to normalize the data, and so that the broader ranges in lower vertebrates, angiosperms, and protists are largely due to this effect. Data are limited to experimentally determined genomes, available from the *D*atabase of *G*enome *S*izes (DOGS).

operators must tell their counterparts if something seems wrong, or when certain problems are not solvable by computers alone. Technical details are useful but principles are extremely important.

2.1 Unbiased Clone Coverage

The essence of achieving unbiased clone coverage lies in making the clone libraries properly, avoiding possible negative effects. In a large SGS project (say for a 500-Mb genome and 6x genome coverage that is calculated as genome size divided by average read length or 6x 500 000 Kb/0.5 Kb = 6 million sequence reads), the first 4x sequence coverage is to cover the target sequence evenly and sufficiently. In this regard, the insert size of clone libraries should be small, usually approximately 1.5 Kb or twice the size

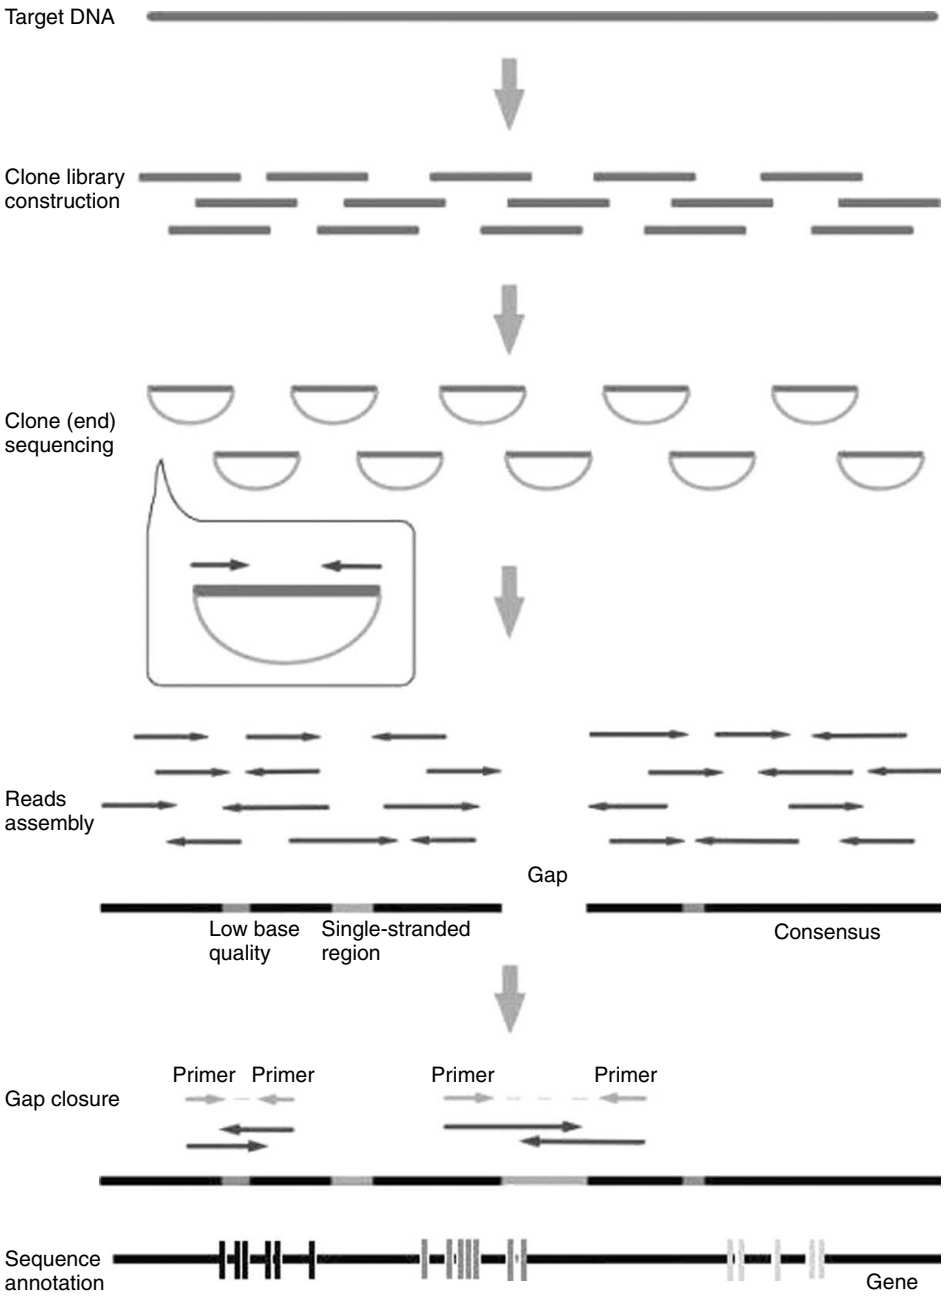

Fig. 6 A schematic illustration of the SGS strategy. Starting from a target DNA, the strategy contains five essential steps: clone library construction, clone (end) sequencing primed by universal primers from vector-borne sequences, reads assembly, gap closure, and sequence annotation. The inset illustrates that the sequencing is done from clone ends with universal primers. Detailed processes are described in the text.

of an average read length. The merits of smaller inserts are multifold. They pose fewer problems for cloning efficiency, randomness, DNA preparation, and sequence assembly. It is also easier to achieve uniformity in size fractionation since DNA fragments of such a size are readily separated in agarose gel electrophoresis. The next 2x is for accomplishing contiguity, and so the insert size should vary according to the repeat contents, including types, ages (in an evolution sense), cluster sizes, and whether there are active transposons that often litter nearly identical repetitive sequences in the genome. When numerous, they create real problems for sequence assembly. The choices of insert size and cloning systems are abundant, anywhere from 5 to 10 Kb for plasmids, from 20 to 30 Kb for mini-BACs, and from 35 to 40 Kb for cosmids or fosmids. BACs are always end-sequenced because in all cases BAC libraries are usually made for building physical maps and targeted gene sequencing, and often constructed before a sequencing project is launched. The only wet-bench concern is that sometimes DNA of large-insert clones is not easily prepared in the same way as small-insert clones and is a poorer substrate for standard sequencing reactions. A subtle computational concern is the ''interleaving'' problem, where repeat clusters are a few-fold smaller than the size of a large-insert clone and longer than a few sequence read lengths, such that sequence contigs between the two end-sequences could be lost (1.2 and 2.3).

Inadequate clone coverage always results in both sequence and clone gaps. Depending on the compositional dynamics of the genome and the data quality (mostly the average of sequence read lengths), sufficient coverage ranges from 6x to 8x. More often than not, a WG-SGS stops at 4x when contiguity is not a major concern. The Lander–Waterman curves are commonly used for estimating such coverage. The growth of number of contigs can be followed closely while the project is ongoing. The only variable for fitting the curve is the average read length when a genome size is known. The read length can be estimated in several ways. The most popular one is to use the Q values calculated by Phred. The value Q20 cut-off (a base error rate of 1 : 100) is adequate for this purpose although hard-nosed sequencing operators sometimes use Q30 (a base error rate of 1 : 1000) for assembly quality measurement. The reads in a length shorter than 200 bp should not be used for the measurement but they can be incorporated later into the final assembling process. Another way to estimate read length is to calculate the fraction that contributes to the consensus sequence. No matter what is used for the read length estimates, more sequence coverage (redundancy) is always a faithful friend during a project that is pressed for time. Sequence read coverage could be pushed up to 10x for smaller projects, such as a bacterial genome. After redundancy is maximized, anomalies should be carefully inspected in an assembly, not limited to assembled contigs and remaining gaps, physical or sequence, but also leftover singlets (stand-alone sequencing read) or singletons (short contigs that are single-read length and assembled by a coverage lower than average). Finishing strategies should be plotted with special attention to the distribution of physical gaps and the nature of sequence gaps.

2.2 Sequence Quality Control

Poor sequence quality that can be improved experimentally usually comes from

poor DNA preparation, since reagents and equipments are all provided by a supply company and process-optimized. Average read length at Q20 is a superior estimator of daily assessment of data quality, and feedbacks from the analysis to the wet-bench operation are necessary. Read length can be improved in several ways. In addition to better DNA preparation protocols, these include prolonging the separation (run) time, adjusting template concentration, and optimizing sequencing reaction conditions. These should be done and managed separately in a small R&D group, rather than constantly revising pipeline protocols. Poor signal-to-noise ratio is also attributable to poor DNA preparation in most cases, although malfunction of the process prior to DNA preparation may also be to blame, such as poor viability or growth of bacterial cultures. System contamination and malfunction of sequencing reactions can also result in poor signal-to-noise ratios.

2.3 Repetitive Contents

All genomes seem to have repetitive sequences; some are simple and others complex. Repetitive sequences can be defined in two ways: mathematically (mathematically defined-repeat or MDR) and biologically (biologically defined-repeat or BDR). When a sequence of a given length is seen in a genome more than once, it is mathematically defined as a repeat. The only variable is length that depends on the complexity or the size of a genome (assuming a random model for four nucleotides). BDRs are functionally defined and usually refer to *sequence-recognizable transposable elements* that are prevalent in genomes of all life forms. BDRs are usually identified with a software tool (such as RepeatMasker) composed of a database and a search engine. Since BDRs have to be identified by sequence homology, there are several problems in classifying them. First, the discovery of BDRs is very much limited by prior knowledge of their existence although fragments of the repeats are easily defined as MDRs. Second, it is difficult to classify BDRs because they do diverge over time according to a neutral rate of sequence mutation and some of the transposable elements are known to be old, such as LINE (long-interspersed-nuclear-element) in vertebrate genomes. Third, BDRs are often fragmented because of the dynamics of DNA sequencing of a genome (such as mutation and recombination) and the biological nature of various transposons (such as active and nested insertion). Therefore, parameters of a search engine can be adjusted to maximize or to ignore certain diverged BDRs, but to find them all is an unattainable goal. The quantitative relationship among MDRs, BDRs and apparent BDRs (BDR's) is depicted in Fig. 7.

Two basic parameters are always a concern for repetitive sequence analysis: the length of repeats and their complexity in a given genome. There are three additional lengths to be aware of in the analysis: those of a read, a clone, and a targeted DNA fragment (such as a chromosome or a genome). When two sequence reads are nearly identical, their positions in the target sequence become ambiguous, especially when sequencing reads are highly redundant for covering the target. In this sense, the smaller the target size, the easier the assembly process. However, when complexity of a target DNA and density of repeats are both high, it poses a serious problem that often results in sequence gaps in the target sequence. In practice, the

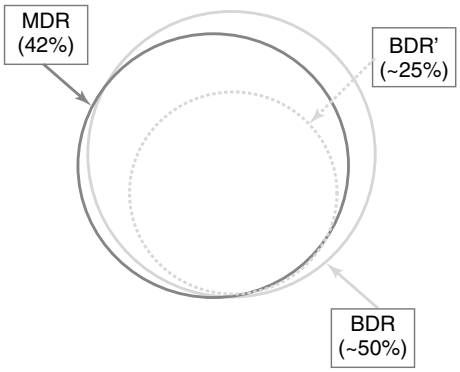

Fig. 7 Distributions of MDRs and BDRs in the rice genome. MDRs can be defined precisely (solid line) by counting exactly repeated elements in a genome. A portion of BDRs (broken line) is defined by degrees of homology (>50%) to known transposon families. The rest is too divergent over the evolutionary timescale to be readily identified but they are clearly present in the genome (gray) and can be estimated through homology analysis with low stringency.

longer the read length (assuming high quality), the less an assembly suffers with sequence gaps. Subclones of SGS project with slightly larger inserts will sometimes help in eliminating sequence gaps but cloning efficiency, size variation due to limited separation power of agarose-based electrophoresis, and other technical details will limit the increase of insert sizes.

2.4 Physical and Sequence Gaps

There are essentially two types of gaps encountered in sequencing a genome. When there is no clone available to bridge two contigs in any libraries for mapping and sequencing, a physical gap is inevitable; it is thus also called a *clone gap*. It is difficult to close such gaps because technology to carry out targeted cloning directly from isolated DNA of a large genome has yet to be developed. It is, however, possible to measure the lengths of gaps by using standard Southern techniques. The reasons for this type of gaps are often complex, but the gaps are usually the results of either inadequate coverage of the library or poor clonability of the missing DNA. Employing directed PCR amplification, adding coverage to the existing library and changing the cloning system, and varying the insert size are all useful remedies, coming from the wet-bench part of a sequence operation. The other type is sequence-related, in which a sequence assembly remains fragmented. In such cases, computer-aided analysis is required to provide clues for the wet-bench workers after they promise to deliver data quality, and have clones of various types in hands. If the nature of the gaps (oftentimes they are either nasty repeats in eukaryotic genomes or toxic genes in microbial genomes) is worked out, they can be left alone after some measurements on the gap sizes. In any case, a finishing plan should be drawn to handle the two types of gaps before they become a problem for sequence analysis, since the more gaps a project has, the more contigs have to be ordered. In a WG-SGS project, at least some effort has to be devoted to sequence finishing because genes or parts of genes may get lost in a massive number of contigs when sequence coverage is low (such as 4x).

2.5 Validation of Sequence Assembly

Multiple estimators should be used to validate a sequence assembly, because oftentimes estimators are biased because

of differences in community interests, emphasizing either functional or targeting aspects preferentially. The available resources are (1) full-length cDNAs and EST clusters (Unigenes); (2) physical maps and their markers (STSs); (3) genetic maps and markers; and (4) close-related genome sequences.

There are three essential parameters to be measured in validating an assembly. The first is average coverage, which can be calculated in a straightforward way such as a percentage of hits of the markers and sequences aligned to the target assembly, although the definition of a hit is always subjective because of the subtle details involved, such as real sequence polymorphisms. The second parameter is to determine how complete those matches are from a study of the markers and sequences to the targeted assembly. The exact matching sequence has to be statistically presented precisely down to each basepair. None of the above parameters would tell much about the correctness of the assembly in terms of long-range contiguity and local misassemblies except in the case of using restriction-digest (fingerprinting)-based physical maps in which the digested fragments are precisely size-measured and even ordered. A retrospective comparison between the sequence assembly and its corresponding physical maps, from a BAC clone or genome-wide, is always an excellent estimator for sequence validation. It is, however, difficult to assess contiguity and accuracy of an assembly when resources for estimation are sparse.

2.6 Integration of Genomic Information

Together with the rapid increase in genome sequences, data integration at multiple levels from genomics-scale studies is of the essence for understanding the basic genomic information and functional annotation of sequenced genomes. In a vertical integration scheme, the top layer consists of genes (their structural and regulatory elements) and other basic genomic elements (repeats, telomeres, and centromeres). The intermediate layer includes gene expression information, from mRNA to protein. The bottom layer is the relationship of a gene product, RNA or protein, and its interacting partners in the context of location (defined by spatial connection and timing), function (defined chemically or physiologically), and mechanisms (defined by specific roles of each of the components and their cooperative functions). Genetic information, including markers and sequence polymorphisms, is usually gene-centric or marker-centric and must be integrated into the top layer as part of the physical map before correlations can be made precisely between genotypes and phenotypes. Database systems are usually built not only to manage and search the raw data. They are also integrated with software packages for visualizing, editing, annotating, and analyzing the data. An integration scheme for rice genomic data is illustrated in Fig. 8.

3 Technical and Experimental Basics

SGS as an operational entity, especially in LSS, is highly specialized, with more than 10 years of experience in process improvement and automation. It is relatively mature in the sense that its basic process cannot change overnight. For instance, sample preparations and all subsequent liquid handling procedures are based on microtiter plates with 96 and 384 wells. The

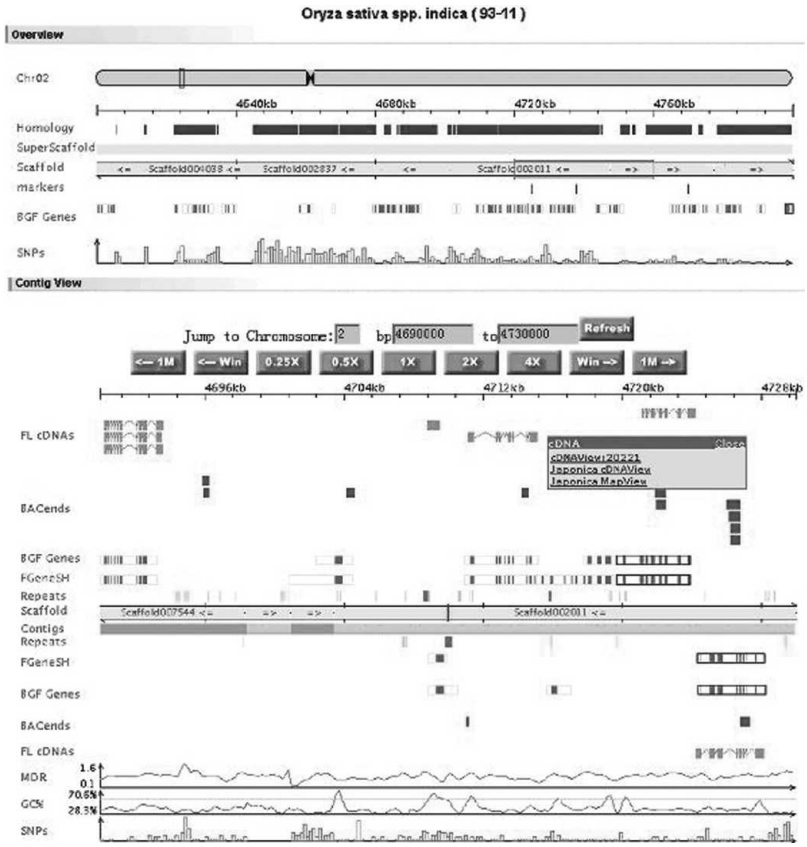

Fig. 8 An example of sequence annotation schemes from the rice genome. Gene-finding results from two gene- finding software packages, FgeneSH and BGF are shown in the annotation.

sequence technology may change some day in the future, but sequencing and cloning systems will live on.

3.1 Genomic DNA Libraries

The preparation of insert DNA is one of the crucial steps in making SGS libraries. For constructing small-insert libraries or subcloning of large-insert clones, physical power, rather than enzymes, is usually preferred for shearing DNA into fragments. There are two ways of doing this – sonication and nebulization. Commercial instruments are readily available and a skillful technician can easily master the technique even for large-scale operations. Partial restriction-digest is not commonly used for preparing insert DNA, especially in large batches. It is, however, very useful when clone libraries with insert sizes ranging from 5 to 20 Kb are constructed for achieving better contiguity.

Size-selection of insert DNA is another important step in securing high-quality libraries, but this is often neglected. Better performance in size-selection results in

not only narrower insert size variation but also lower numbers of ''empty'' (a consequence of too small an insert) clones, thus improving the standards of library quality control. A more uniform insert size is very helpful in sequence assembly when information on clone ends is used to join contigs (3.3). To achieve a better size-selection, two key factors should be kept in mind: electrophoretic conditions, and appropriate loadings (micrograms of DNA per well in an agarose gel). Rapid electrophoresis, by increasing either currents or voltages of the electric field, reduces separation power, while overloading damages the filtration power of the matrix (agarose). For this simple but key step, an optimized system should be carefully established.

3.1.1 Source DNA

One can never over-emphasize the importance of selecting source DNA for a genome project, regardless of whether WG or CBC was used as the downstream strategy. The potential problem lies in the genetic heterogeneity of DNA samples. It is only a minor problem in large organisms because they have sufficient tissue or body mass, but in small organisms of which tissue samples from multiple individuals are used for extracting genomic DNA, it can be a major problem. In the case of sequencing small-sized genomes, such as those of bacteria or archaea, DNA samples should be prepared starting from single colonies. When different batches of DNA preparations are unavoidable, special care should be given to watch for transposon insertions and segmental duplications. Such a situation pleads for restriction fingerprinting analysis (using pulse-field gel electrophoresis if necessary) to make sure of sequence integrity among the samples. For small multi-cellular organisms such as worms, insects, and small plants, it is crucial to prepare genomic DNA for library construction from a homogenous (inbred) population. It is not unheard of that a WG-SGS project might have to be abandoned because of the impossibility of attaining assembling sequence reads at an identity of 95 to 99%. When a non-laboratory strain has to be used for a project, physical maps should be built with large-insert clones, from which a set of MTP clones is fed into sequence pipelines. It thus becomes a CBC-SGS project. Extreme caution should be exercised lest other invisibly small organisms contaminate the source DNA isolated from a wild species, especially those from open waters, such as large protists, small marine animals (mollusks, sponges, and corals), and miniature plants.

The final concern, though not the least, is about sex chromosomes. In a sexual organism, sex chromosomes are often unevenly distributed between males and females. Other than human males who have a miniature sex chromosome, Y, sex chromosomes in other sexual species are sometimes comparable in size. However, they may not have the same distribution as human sex chromosomes, where XY is male and XX is female. In birds, the male is homozygous, ZZ, and the female is heterozygous, ZW. Oddities are often observed in life forms, with even temperature and crowdedness being determinants for sex and genetic makeup. Whenever possible, a haploid genome provides much better source DNA for WG-SGS.

3.1.2 Quality Assessment

There are a few parameters to be measured experimentally to assess the quality of an SGS clone library: the average insert size, the rate of non-informative clones

(small inserts and background vector self-ligation), and clone recovery rate. The first two parameters can be measured by colony-PCR (using a small number of bacterial cells as PCR templates after heat-denaturation) or by sampling isolated plasmids. To avoid false-negative results of PCR, tested samples should be in duplicates with appropriate controls. The last parameter is a result of several potential tribulations, including mixed or defective clones, and non-optimal growth conditions. It has to be tested by sequence sampling. For a large-scale operation, it might be more economical to just test all the parameters by sequencing random samples.

3.2 Sequencing Data Acquisition

The sequencing data acquisition process is the engine of SGS. It is calibrated in a very subjective and precise way as throughput and cost. The throughput has shaped the way LSS is organized globally, with only a dozen or so academic institutions being focused on such an operation. The cost structure of DNA sequencing is composed of capital equipment, reagent/supply, and labor. At least two-thirds of the total cost is on account of reagents and supplies, so there is still plenty of room for cost reduction. Another important factor is the management of the two major components of sequencing business: one, the experimental process, and the other, computation. Only a short feedback loop between these two components can ensure operational efficiency.

3.2.1 WG-SGS and CBC-SGC

Operationally, there are major differences between CBC-SGS and WG-SGS. First, CBC-SGS is a map-directed operation and it relies heavily on the completion of a physical map containing targeted regions. In most of the multi-institutional operations, work is allocated according to chromosomal regions (in the case of HGP) or simply individual chromosomes (in the case of the international rice genome consortium). A potential danger is that loosely affiliated members may all have their own priorities and agendas, and that their schedules for carrying the project to the finishing line may vary accordingly. As a result, the satellite projects have to be finished and published separately; such an operation not only reduces the scientific impact of a project but also faces the risk of being ''scooped.'' WG-SGS is in a much better position to succeed, since data are to be acquired by the same group or groups with comparable operating styles. Second, CBC-SGS requires an intermediate management layer to handle maps and clones, to construct more shotgun libraries, and to assemble each clone, each of which requires a different sort of attention to complete. In other words, wherever genomes with high repetitive sequence contents are involved, they may never be finished to a similar standard, and therefore CBC-SGS could face a disastrous situation. Large plant genomes are illustrative of such cases, where the repeat contents exceed gene contents. For smaller animal genomes, however, the problem is less hazardous. Third, WG-SGS poses major challenges for sequence assembly when the target genomes are large and contain high repetitive content, but assembling sequences for large-insert clones in typical CBC-SGS are not. In CBC-SGS, sequence contigs are ordered according to clone orientation in physical maps, whereas in WG-SGS, contigs can be ordered within scaffolds or according to physical markers. In some cases of WG-SGS, contig and scaffolds may not be ordered until

both physical and genetic maps become available. WG-SGS data, however, provide a foundation for retrospective physical (gene) and genetic mapping efforts.

3.2.2 Directed Cloning and Random SGS

During the early phase of LSS, there were two essential strategies developed to evaluate the cost and efficiency for an operational process. The first system utilized a random shotgun protocol and M13 phage (single-stranded DNA) cloning system. DNA preparations for M13 cloning, when carried out manually, are usually easy and clean, giving rise to high-quality sequences. It is unfortunate that only one end of the single-stranded DNA can be primed for sequencing. The method was soon replaced because the success of a complex experimental protocol depends on the collective merits of all the procedures. The second system is the plasmid cloning system (double-stranded DNA). Two simple advantages of using plasmids are: sequences from both ends of the insert are obtainable from a single DNA preparation, and the length of DNA inserts is also a piece of powerful information for sequence assembly when their sizes are prepared relatively uniformly. Although other attempts were made in the early days of LSS, such as transposon-directed plasmid sequencing, the current practice is focused on a plasmid-based random cloning system, oftentimes coupled with controlled insert sizes.

3.2.3 Process Control

SGS remains merely a process rather than an approach or strategy when it is not evaluated and compared with other sequencing techniques. It is quite complex, involving integration of sequence acquisition, data processing, and analysis. As a process, it has to be versatile because relevant technologies are still underdeveloped and any part of it can be changed over a short period of time. For instance, capillary sequencers now dominate all large-scale sequencing operations, although the slab gel format may continue for special purposes such as for small-scale operations and for achieving longer read lengths. Of course, the most practical consideration in building a sequencing operation has to be capital investment. Any such investment on a process-unstable technology should be carefully calculated. With an estimated annual budget exceeding $1 billion US dollars globally for large-scale genome sequencing, more than half of which comes from public funding agencies worldwide, LSS is undoubtedly going to stay with us for some time.

SGS creates major managerial challenges for process control. On the wet-bench side, the managers are Ph.D. scientists and skillful technical staff, who are able to master cloning techniques and to have troubleshooting capabilities for all protocols used; each has precise quality-control parameters that are under close surveillance with fast feedback loops. For instance, whether or not a clone library is going into the pipeline depends on its "pass rate," in which contaminations from *E. coli* host and vectors, average lengths of the insert, and identities of the target sequences (such as signature repeats) are all factored in. However, things can go wrong in between too, such as failures in DNA preparation and sequencing reactions, equipment-related errors, and even data tracking mistakes. In most of the cases, a custom-designed software system has to be implemented for a process-controlled operation. The challenge in building a robust system is to decide on the extent

of automation *versus* human intervention, where fully automated systems are impossible to build. On the computing side, things are even worse. Data of different kinds are voluminous and instantly accumulating, including raw trace files (calling for data management and database building) from different projects (calling for project management when target DNAs are from different sources), quality assessment (involving quality management to distinguish usable and unusable data), assembled intermediates (requiring process management dealing with reads, contigs, and scaffolds), and annotations (calling for biological research to interrelate the results by searching against all available data); and even these data are always incomplete. Because automation is being continually expanded, other groups of people have also entered the process, namely, engineers and manufacturers. Three indispensable groups with different cultures have to work together on the same process. When physical mapping is involved, another group of people would have to join this outsized team.

A process should be evaluated by its throughput and efficiency. There are many reasons for there being only a few large genome centers to do the basic jobs, but management and experience matter the most. In addition, scales, automation, and robust protocols are all major concerns for a sizable sequencing operation. As the size of the target genome gets bigger, the scale of an SGS operation goes up. Currently, projects of the size of mammalian genomes (3 billion basepairs) are usually handled by a joint effort of more than one genome center. There are only half a dozen genome centers in the world that are able to handle the sequencing of large genomes independently.

3.3 Sequence Assembly

Sequence assembly is the most time-consuming and computing-intensive part of SGS, especially for WG-SGS. Software tools for sequence assembly, and also for gene-finding and sequence annotation, have to be developed and implemented before a real project starts. In addition, the skills and experience of the operating teams are also important since the entire process is very complex and demanding, as is described below.

3.3.1 An Overview of General Procedures

There are distinct steps in the procedure for sequence assembly. First, repetitive sequences need to be defined, classified, and masked for each sequence read before being placed into an assembly pipeline. Second, low-quality reads (usually at the ends of a sequence read) and contaminated reads (from library hosts and other projects) are removed through different computational filters. Third, computer-assembled sequence contigs are evaluated based on mathematic models (such as the Lander-Waterman model) and examined manually after each finishing protocol is applied (3.4). Fourth, contigs are further linked into scaffolds based on additional information. Finally, contigs and scaffolds are ordered and oriented according to chromosomal organizations based on physical markers or other experimental data, such as those from fluorescent in-situ hybridization (FISH).

3.3.2 Classification of Repetitive Sequences

Almost all eukaryotic genomes contain significant portions of complex repetitive sequences. Despite the fact that these repeats are mostly definable by their

repetitive natures, being created over evolutionary timescales, they have not only jumped in and out of genomes at different points of time (lineage-specific) but are also being mutated and recombined among themselves, making their precise identification an intricate task. Repetitive sequences are often classified into two basic categories, simple and complex. Simple repeats are easily definable and of less concern for sequence assembly, because they usually constitute only a small percentage of the genome sequences in vertebrates and seed plants. They do occasionally pose minor problems for sequencing (3.4.3) and may become a major nuisance for insect genomes, as they could account for a major part of heterochromatins. Complex repeats are mostly defined biologically by detailed evolutionary analyses and by building sequence libraries for featured annotations of discrete taxonomic groups (2.3). Another class of repetitive sequences is the so-called *low-complexity repeats* (LCR). The origin of LCRs is recent segmental duplications, and they may cause significant problems when concentrated in a proximal region of a chromosome. However, they are not very frequent, and experienced researchers can deal with them quite easily with the aid of denser physical markers and unique sequence signatures. The final class of repeats concerns special regions of chromosomes, such as centromeres, telomeres, and their nearby regions, such as subtelomeric regions. Different research groups usually handle these repeats according to their own specific interests.

3.3.3 Software Packages for Sequence Assembly

Sequence information is acquired through an electrophoresis-based instrument that is capable of resolving differences among DNA fragments at single base level. An important parameter is the quality of each resolved base, which is measured as error probability or error rate. In the most popular software package for sequence assembly, Phred-Phrap-Consed developed by Phil Green and his colleagues, Phred is a base caller that is capable of assigning an error rate to each sequenced base from a machine-processed trace file. Using stringent quality measurement, all eligible bases are used for assembly. Phrap carries these quality scores when it assembles consensus sequences from a set of sequencing reads. Consed is essentially a viewer that allows users to examine the results and edit the sequences. Nearly all sequence assemblers have capabilities similar to the Phred-Phrap-Consed package, but some have been outfitted with more user-friendly features. For instance, CAP, another sequence assembly program developed by Xiaoqiu Huang and Anup Madan, is able to clip 5′ and 3′ low-quality regions and uses forward–reverse constraints to correct assembly errors. Phusion, an assembler developed at the Sanger Institute, is competent in assembling mammalian genomes, and was used in the mouse genome project with a WG-SGS dataset. Phusion incorporates end-pairing information and has an ability to group large numbers of sequence reads before performing a parallel assembly protocol. Some of the major software packages for sequence assembly are listed in Table 2.

3.3.4 Building Contigs and Scaffolds

The fundamental nature of sequence assembly software is to define identity among sequences of different reads and to detect their overlaps. Several software packages have been developed for DNA sequence assembly but by far the most

popular one is the Phred-Phrap-Consed package. For large WG-SGS, a special package has to be built in to handle additional information that is not dealt with by Phrap. For the purpose of illustrating the basic principles and methodology, RePS (an assembler, *re*peat-masked *P*hrap with *s*caffolding, developed at Beijing Genomics Institute) is taken as an example (Fig. 9).

The first step of a sequence assembly is to define ''repeats,'' and these are the major obstacles whenever sequence comparison is the engine of an assembler. Repeats are usually defined mathematically as exact matching sequences of oligonucleotides (MDRs), as a series of ''oligomers.'' The lengths are often defined empirically, such as 20mers for large eukaryotic genomes. Repeats are identified from each sequencing read and ''masked'' before being placed in an assembly process. Some of these reads may be completely masked so that they have little chance to contribute to intermediate assemblies, but they are factored in as anonymous coverage only in the final product. Phrap is often used as an assembly engine for most assemblers although other algorithms have been developed for general sequence comparison and assembly.

In nearly every LSS project, another powerful piece of information is also used, namely, paired sequence reads from the ends of the same clone (acquired from opposite directions), which allow users to order and orient additional contigs that are not obviously overlapping in sequences but definable by clone-length criteria. When the insert sizes of a clone library are not significantly deviated from a median (usually measured experimentally), a uniform size is assigned to all the clones sequenced from both directions. The insert sizes may vary among libraries used for a particular project but not within the libraries. As a result, the ends of a clone can be paired, though sequences of the middle portion of an insert may not be covered from both ends, and this information is utilized to ''scaffold'' neighboring contigs that are anchored by these end sequences. Figure 9 depicts the assembly process involving the two primary components of RePS: assembly of repeat-masked reads with Phrap, and scaffolding based on clone-end information.

The final process of an assembly is to close the gaps. At this point, two types of gaps are in evidence: artificially created ones due to repeat masking, and physical ones that occur statistically by chance. The former is referred as *repeat gaps* (seen within sequence reads) and the latter is called *Lander–Waterman gaps*. Repeat gaps can be filled after reads are assembled and Lander–Waterman gaps are to be closed experimentally because they often result from inadequate coverage or purely by chance. In practice, both gaps are usually smaller than the lengths of single reads and can be bridged by clone-end information, when paired ends of a clone happen to join their two neighboring contigs.

3.4 Sequence Finishing

Sequence finishing, a process for achieving better contiguity of a target sequence, is always a time-consuming process, and requires the collective experience in LSS built up over a decade. Efforts in automating such a process have had some successes, but have suffered because of the inadequacy of standards as well as funding. There is no question that certain important genomes have to be finished

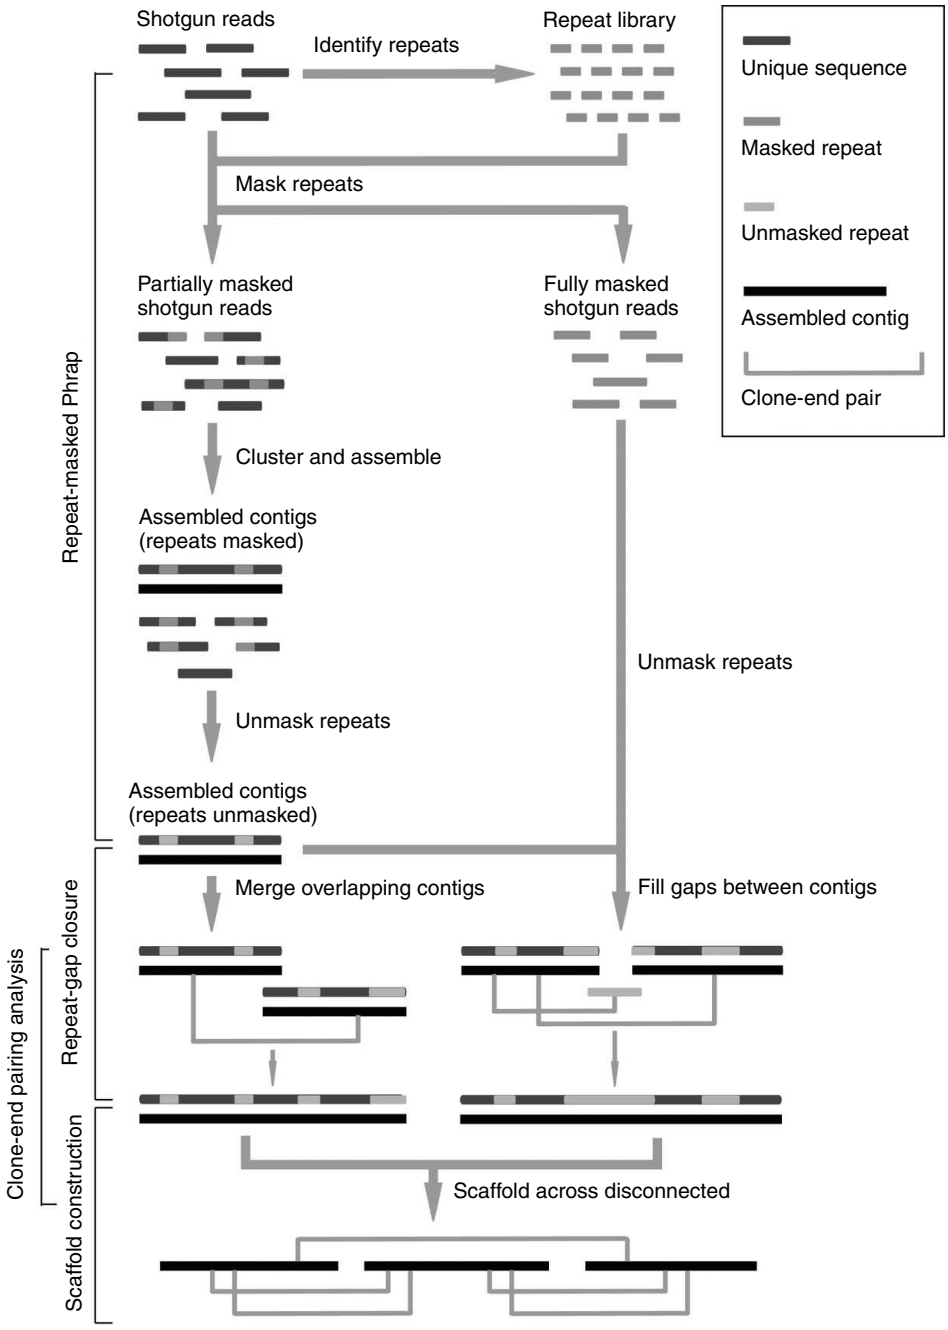

Fig. 9 Schematic flowchart shows the process of sequence assembly.

to a standard that is acceptable to the scientific community. Examples of such genomes are the human and laboratory mouse genomes, but for other genomes a working draft (6–8x coverage) as the final product of a genome project should be satisfactory. With either WG-SGS or CBC-SGS, the basic finishing process for sequence gaps is essentially the same. It includes: (1) improving quality in the weak regions (often defined as those covered by a single read generated from a single type of sequencing chemistry); (2) primer-walking on clones at contig ends; (3) PCR-sequencing to close gaps; and (4) checking consistency guided by physical maps. These activities are normally performed by a team of well-trained technicians and led by a highly experienced scientist with a Ph.D. degree.

3.4.1 Improving Sequence Quality

Before one looks into the relationship among sequence contigs, the first thing to do in the finishing stage is to analyze the weakly covered sequences (poor sequence quality and single-read coverage) that are often the reason for misassemblies and false joints between contigs. Poor reads assembled into contigs should be removed first and repeated experimentally with or without new DNA preparations. Plasmid clones (not M13 clones) can be sequenced from the opposite directions if the poor reads are due to the nature of DNA sequences (such as long simple repeat tracks or extreme GC-contents). This seemingly less impressive practice is in fact very powerful, and at times reduces the number of contigs by half in a project on bacterial genomes of a few Mb in size. The second major effort should be to figure out reasons why certain contigs stop growing; some may be obvious and even straightforward to determine, and others may not. For instance, when contigs repeatedly end with poor-quality reads, the most obvious solution is to add more reads to increase the total sequence coverage. When contigs end with large numbers of reads, higher than the estimated average coverage, and stop sharply with a pile of high-quality reads, the reasons are usually misassemblies due to repetitive sequences. In large genomes, low-copy repeats, which may be either large (such as recent segmental duplications) or small (such as recent transposon insertions and duplications), from time to time create serious headaches for sequence finishers and need to be spotted as early as possible.

3.4.2 Primer-walking and End-sequencing

All sequence contigs end for some particular reason. These reasons include, but are not limited to: (1) low-quality reads or failed sequence in one end of a clone that happens to be in a poorly covered region; (2) high-copy repeats that are too long to be linked by any clones in the assembly; (3) low-copy repeats that are assembled together; and (4) false joints that are made within the contigs. These reasons can be placed in one of two categories: repeat-related and quality related. Quality-related contig-breakers can be eliminated by primer-walking, in which specific primers are designed to improve the local sequence quality. When a PCR product is too long to be ''walked'' over (for example, if it is more than 3 Kb in size), a clone library can sometimes be made from the PCR product for a small SGS project. Repeat-related contig-breakers are, however, very hard to eliminate. Software tools are required to examine sequence contigs and their contents, and to relate repetitive sequences among contigs. In

the assembly software assembly software package, Phred-Phrap-Consed, there is a useful little tool, called *PhrapView*, allowing users to see distributions of repetitive sequences among contigs within a project. A general remedy for the repeat problem is to add some large-insert and end-sequenced clones into the assembly, such as BACs or cosmids/fosmids. The hope is that these long-range sequences can solve, in part, this type of assembly problem. When repeat-related problems are explicitly understood, editing of software parameters and read assemblies becomes an easy solution.

3.4.3 Closing Sequence Gaps

There are always mixed feelings about closing gaps. On the one hand, it is satisfactory to close some simple gaps, such as by PCR-based methods. On the other hand, when thinking about the nature of these gaps, one may wonder why we have to take so much trouble over closing them. This is because most of the gaps are caused by short (a couple of Kb or less), low-complexity (a few unique copies in the genome), and simple repeats (such as {AT}n and {CCT}n). Time and again, gaps are found due to degenerate simple repeats (such as degenerate repeat tracks of pentamers or hexamers, often classified as MDRs, 2.3) that are poorly maintained by the bacterial hosts. In other words, they are mostly physical gaps caused by cloning failures, and are especially present in animal genomes, such as those of human, mouse, and insects. Short BDRs of high density can also result in similar gaps, especially in plant genomes. When large repeat clusters are encountered, gap closure can be difficult and sometimes impossible. Extreme GC-contents, often caused by simple AT-rich or GC-rich repeats, can also result in gaps because they are tricky to sequence with a standard sequence reaction protocol. Both annealing and extension temperatures of a sequencing reaction have to be adjusted to repeat the experiments. In the genomes of grasses and warm-blooded vertebrates, a negative GC-content gradient along the transcription direction exists in a significant portion of their genes. This is the result of a mutation drive that is believed to originate from the transcription-coupled DNA repair mechanism. When the GC-content of these genes reaches 70%, the 5′-end is occasionally missing in the assembly. Though this is a particular case seen in sequencing the rice genome, the phenomenon may extend to other grass genomes (such as those of wheat and corn). In summary, there are no universal rules about how to close gaps, and what the sequence characteristics of the gaps are. It is, however, worth making an effort to close a few gaps just to know what is out there.

It is still debatable whether all gaps should be closed in a genome sequence and it is up to the research communities and their funding agencies to take a final decision. It is our opinion that, in a WG-SGS project, certain gaps should be closed and their sizes measured where feasible; these should include gaps that separate a coding sequence and that are shorter than a few Kb, within a PCR-reachable distance. On the other hand, when gaps are known to be the result of running against long-range repeats, they should not and cannot be closed with currently available techniques. On an experimental note, when closing gaps that are poorly covered by bacterial clones, one can use isolated YAC or genomic DNAs as PCR templates for gap sizing and filling since they may have resulted from DNA sequences that have poor clonability in bacterial hosts.

3.4.4 Physical Mapping and Clone Fingerprinting

Because both physical mapping and clone fingerprinting are very important techniques for SGS, almost all large-scale sequencing projects are initiated along with a parallel project to make large-insert clone libraries. Physical maps can be constructed by using three basic substrates: chromosomal segments (such as radiation hybrid mapping, in which overlapping chromosomal segments are carried by a cell line originated from different species); large-insert clones; and restriction fragments (or even DNA fragments). Two basic markers are used for physical mapping, namely, STSs, and restriction-digest fingerprints. The essence of physical mapping is to order these markers, clones, and DNA fragments. Large-insert clones are the most useful reagents for sequence-ready physical maps, especially BCAs and cosmids/fosmids.

In CBC-SGS, physical mapping becomes a prerequisite and a sequence-ready map is the starting point for large-scale SGS. Since BACs (100 Kb to 200 Kb) and cosmids (30 Kb to 40 Kb) and also fosmids and phages are better sequencing substrates than YACs, both directly (such as for end-sequencing) and indirectly (their subclones are the direct substrates), they are preferred for constructing a sequence-ready map. YACs are generally useful for long-range physical mapping, such as YAC-based STS mapping, but they have to be subcloned into cosmids or fosmids again in order to make a sequence-ready map. For WG-SGS, it is foreseeable that physical maps will be needed for hanging sequence contigs or scaffolds on chromosomes when projects on large genomes are carried over their SGS phase. With unlimited STS candidates in hands, it is quite feasible to construct a contig-based STS map retrospectively, even if the number of scaffolds may exceed a few hundreds. Another way to order sequence contigs is to use the FISH technique, in which representative large-insert clones can be placed and ordered over chromosomes experimentally.

Clone fingerprints are also useful in validating an assembly, especially for CBC-SGS. When large-insert clones are fingerprinted with high redundancy, each clone and also the genome-wide sequence quality can be systematically checked, aided by software tools such as FPC, which is an integrated program for assembling sequence-ready clones, developed at the Sanger Center.

3.5 Genome Annotation and Analysis

Genome annotation has now become a specialty in genome-sequencing projects. It gets more and more complex because data of different types are being accumulated exponentially and most of them are cross-referenced both vertically and horizontally. In a vertical sense, data of a single species have to be integrated from genome to transcriptome and proteome, as well as information from other levels of functional studies (such as metabolisms, networks, and interactions). In the future, all data that can be cross-referenced will be cross-referenced without any delay. In the horizontal sense, data from closely related species (within a species, genus, and even within the same phylum) have to be compared and analyzed with regard to the details relating to the genes and their functions. The norm is going to be changed over time until species representing all life forms of the extant taxa have been somewhat sequenced. This is not a dream but a future reality.

3.5.1 Compositional and Structural Dynamics

Genome sequences are dynamic entities, deriving from common ancestral genomes, and evolving to become more divergent, complex, while remaining related at different evolutionary scales. Eukaryotic genomes are known to undergo compositional transitions driven by mutation mechanisms that are by and large governed by various DNA polymerases involved in DNA replication and repair. Although eukaryotic genomes with extreme average GC-contents are rare, heterogeneous distributions of DNA composition are regularly observed. Figure 10 shows several examples of such a dynamic nature. Major compositional transitions have been discovered among genomes, between warm- and cold-blooded vertebrates, and between grasses (one of the major monocotyledonous plant groups) and the majority of dicotyledonous plants. Moreover, not only is such an increase in GC-content directional (Fig. 11), from 5′ end of the transcription unit toward its 3′ end, but it also involves significant portions of the genomes and highly expressed genes. The exact molecular mechanism has not yet been demonstrated experimentally, but it is speculated that it could be largely attributable to transcription-coupled DNA repairs. The relevance of genome compositional dynamics to SGS is multifold. Extremes of GC-content (lower than 20% and higher than 60%) often pose problems

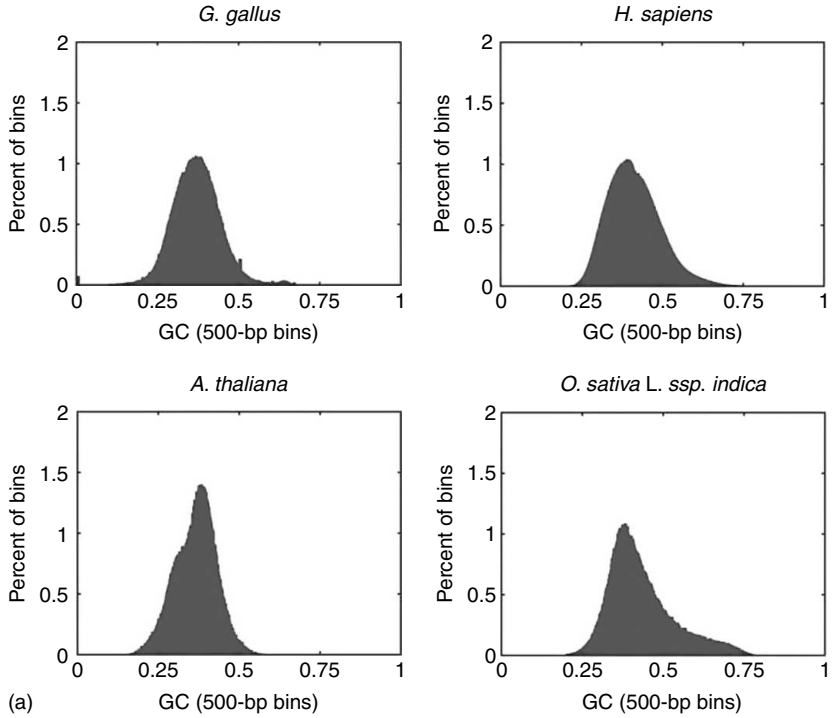

Fig. 10 Genomic GC-content distributions of selected genomes: *G. gallus, H. sapiens, A. thaliana, O. sativa, D. rerio, X. laevis, C. intestinalis*, and *C. elegans*. GC-contents are computed over a bin size of 500 bp.

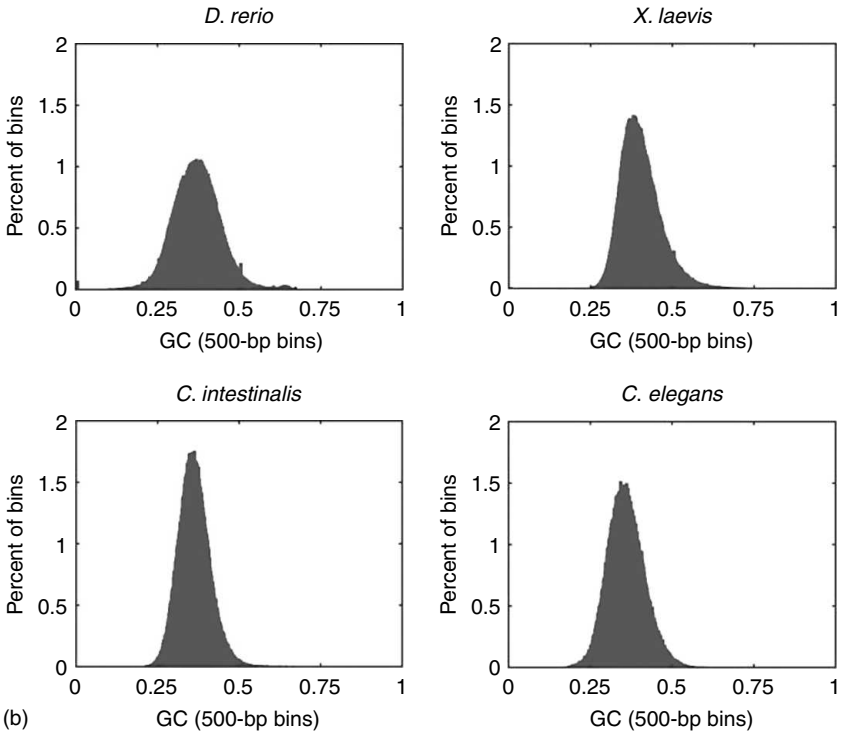

Fig. 10 (*Continued*)

in cloning and sequencing procedures. Sequence heterogeneity interferes with gene-finding algorithms, especially when training data sets are not readily available. It also biases sequence homology comparison, making genome annotation more difficult.

The structural dynamics of evolving genomes are studied at higher levels than single or a few dozen basepairs, generally involving large duplications and deletions, which could occur genome-wide and in the whole genome, in a chromosome segment, and at gene levels. Broadly speaking, structural dynamics within genes and gene families should also be dealt with in a similar way, such as alternative spliced variants and differential gene expression though transcription mechanisms. In-depth understanding of genome and gene structural dynamics is of importance in genome assembly and annotation.

3.5.2 Genome Annotation

The keys in genome annotation are gene-finding and information integration of experimental evidence and, to a lesser extent, repeat identification. For LSS, these are always handled with automated software tools and organized in databases. Table 3 lists some of the major sequence, genome, and annotation databases as well as their relevant information.

Since sequence data are being accumulated much faster than experimental evidence, development of *ab initio* gene-finding software becomes a major research activity for bioinformatics. Table 4

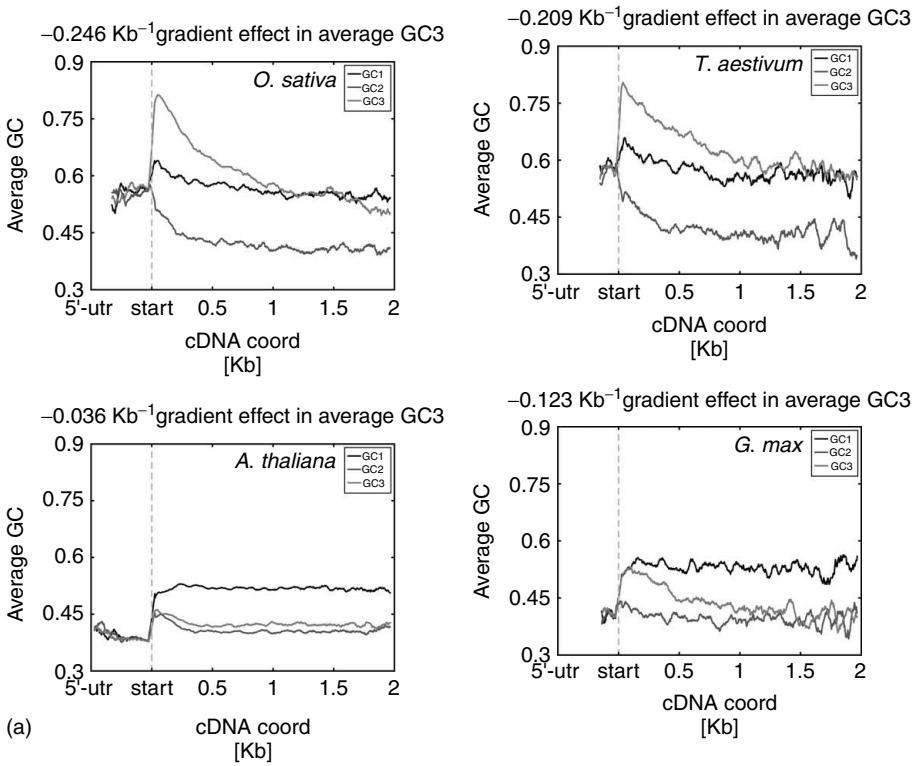

Fig. 11 GC-content increases in cDNAs of plants and animal genomes. GC1, GC2, and GC3 content are plotted as a function of cDNA position, relative to the start of the coding region, and averaged over all cDNAs with a 51-bp sliding window. Phase information is extended into the 5 -UTR. Eight examples are shown here: (a) from plants, *O. sativa*, *T. aetivum*, *A. thaliana* and *G. max*, and (b) from animals, *H. sapiens*, *G. gallus*, *D. rerio*, and *X. tropicalis*.

shows selected examples of such software packages, their methods, and immediate applications. Regardless of which mathematical model (Hidden Markov Models or neural network) is used and what parameters (sequence composition or signal to weight), a common misperception about gene finding is that a universal logarithm must be developed for all genomes. In addition to support from experimental evidence, two common factors that determine the performance of a gene-finding program are sensitivity (a measure of prediction that is equivalent to one minus the false-negative rate) and specificity (a measure of prediction that is equivalent to one minus the false-positive rate). These two parameters often obscure the possibility that there are classes of genes for which the performance is exceptionally better or worse, such as those in different size classes. It is necessary to consider how performance varies as a function of some continuous variables that describe the properties of a test gene set. Gene size as a variable is particularly important in predicting genes for animal genomes because most of them are accounted as gene

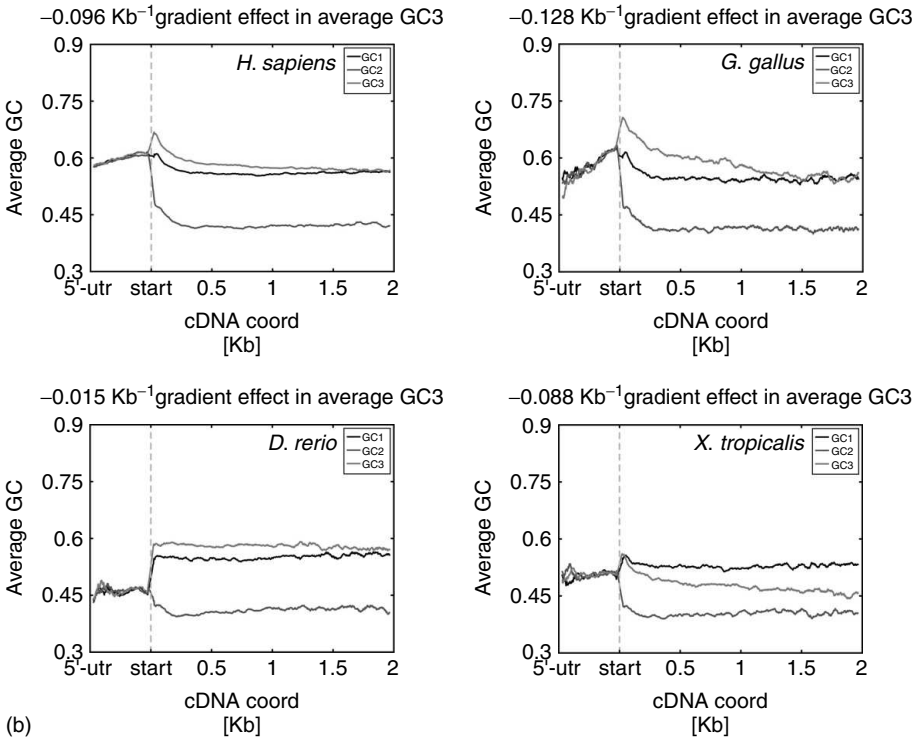

Fig. 11 (*Continued*)

spaces (including exons and introns, 1.2). Not only do mammalian genomes contain large genes that are megabases in size, but insect genomes too are known to have large genes across heterochromatin intervals. Therefore gene predictions should be carefully evaluated and interpreted based on the dynamic features of the target genome. Algorithms that succeed in analyzing one genome should not be blindly used in others, especially when they are by and large unrelated, such as (in an extreme case), between animal and plant genomes.

3.5.3 Sequence Variations

It is becoming increasingly common for a genome project to include an effort to generate sequence variation data through sequence sampling of wild counterparts (the chicken genome project did this in the opposite way, choosing the wild type, the red junglefowl, as the target), diverged breeds and closely related species. The study of sequence variation involves two basic steps: discovery in order to find candidate variations, and validation to acquire frequency information of verified variations in a background population. SGS provides a powerful procedure for the first step and could be used for the second in a rather limited way in consideration of cost differences between sequencing and genotyping. The cost of the latter is believed to be dropping at a much faster pace than that for sequencing.

3.5.4 Genome Evolution

The study of genome evolution in the Genomics Era has focused largely on lineage evolution (such as within vertebrates and fungi) in a vaguely defined context of comparative genomics, but nonetheless on the scale of genomes. Vertebrate genomes appear to be evolving to become more complex, as opposed to insect genomes that are evolving to become more diverged. Complexity has to build upon intricate networks of interacting genes or, more precisely, their products; these intricate networks are in turn defined functionally as molecular mechanisms and cellular processes. It would be of great interest to see how a new mechanism or a new process, created or modified in terms of new genes or

their definable variations over evolutionary timescales, results in building new organs, gaining new functions, and giving birth to new species.

As genomes of major domesticated crops and farm animals (oftentimes also their wild counterparts) are being sequenced, learning the rules that underlie many of the evolutionary changes in an artificial process (domestication) over a relatively short time period (10 000 years or so) should command the attention of many research teams, because of its scientific and economic importance. Ample collections of plant germplasms and animal breeds provide invaluable genomic resources, and domesticated animals can also serve as model organisms for human disease research.

Genome sequences evolve in both macro- and micro-scales. At the macro-scale, there are whole-genome duplications and subsequent chromosomal duplications, deletions, and rearrangements. At the micro-scale, there are gene duplications and deletions as well as enormous sequence variations within genes and gene families, and all are complicated by transposable element insertions over a variable evolutional timescale. Genome evolution should be studied in a much broader context than what has been defined by the classic field of molecular evolution.

4 Other Useful Resources for SGS

The ultimate goal of a genome-sequencing project is to be able to present a whole picture of a genome with all genes positioned on its chromosomes. In the pursuit of this goal, one faces at least two major challenges: identifying all the genes, and ordering them. Algorithms for *ab initio* gene identification are not yet mature, as proved by the fact that the numerous versions of such software have had only moderate success thus far. Under current circumstances, independent data are oftentimes required for a better annotation of the WG-SGS data; these include ESTs and cDNAs for validating the presence of gene transcripts, physical and genetic maps for gene ordering and referencing to inheritable traits, and comparative analysis to exploit evolutionary inference.

4.1 ESTs and Full-length cDNA

When compared with a WG-SGS project, EST sequencing requires little effort. For instance, to cover a 500-Mb genome once, it takes one million reads. To acquire significant coverage for a transcriptome for a given metazoan cell, 10 000 reads ought to be enough. It is worthwhile to allot 1 to 10% of the budget of a genome project to this effort, either as part of the main project or independent of it. As an example, the Sino-Danish Swine Genome Project has initiated a ''one-million EST'' Project, allowing researchers to acquire powerful transcriptomic data from one hundred different tissues and cell types, nearly 10 000 ESTs from each. Table 5 summarizes the top 20 EST collections from the public databases.

Full-length cDNA data are superior, but require much expertise to generate. It involves making full-length cDNA libraries, sequencing cDNA clones that are longer than typical sequencing reads, strenuous management inputs to follow up each clone, and reiterating the libraries for novel clones. Yoshihide Hyashizaki's group at RIKEN and Shoshi Kicuchi's group at NIAS, Japan, have done excellent jobs on

Tab. 5 A list of top 20 EST collections from selected species.

Species	*# of ESTs*	*# of UniGene entries*
H. sapiens	5 657 997	106 934
M. musculus	4 235 142	76 298

C. intestinalis	684 280	14 098
A. gambiae	150 042	14 085
D. melanogaster	382 439	13 928

Note: This list is ordered by the total number of UniGene entries/ESTs by 2004-8-20.

this front to have curated adequate among of human, mouse, and rice full-length cDNAs. Full-length cDNAs do provide irreplaceable resources for gene identification and sequence quality validation, and thus demand independent efforts.

4.2 Physical and Genetic Maps

The mapping of information, whether physical (other than sequence maps that are, strictly speaking, also a form of physical map) or genetic, is always a plus point for WG-SGS. Physical maps allow the assembled sequence and genes therein to be referenced to the chromosomes in physical order, and genetic maps link genes associated with inheritable traits to a physical location on a chromosome through polymorphic sequence sites. For large genomes in the size range over a billion basepairs, such information becomes essential. Another yet-to-be tackled challenge is to map genes on small chromosomes that have no obvious chromosome banding patterns, such as the microchromosomes in the chicken genome and numerous minute chromosomes in the genomes of crabs and shrimps. High-quality WG-SGS is capable of producing an assembled genome sequence map within one to a few scaffolds, which can be mapped physically by several methods, such as different versions of FISH and large-insert clone-based physical maps. Since both mapping processes are expensive, time-consuming, and resource-demanding, they can be constructed retrospectively after a WG-SGS, over a period of time. Nevertheless, sequence data, nevertheless, provide ample candidate markers from genes, microsatellites, and even SNPs, for mapping activities. Physical mapping methods are essentially based on three laboratory techniques. The most common technique is restriction digests of large-insert clones, or clone fingerprinting. It relies on redundancy and precise fragment size measurement to determine overlapping clones, and thus achieve ordering. The second technique is large-insert clone-based STS mapping. It leverages PCR technology and calls overlap according to whether the large-insert clones share short unique sequences in a given genome. The third technique is hybridization-based, in which short oligonucleotide sequences (also termed as sequence-tagged connectors generated from end sequences of large-insert clones) serve as probes to tag clones that are gridded in a very high density on reusable nylon filters.

Genetic maps are always needed for genetic and functional studies, where the relationship of each locus is linked by the frequencies of a recombination event as measured in pedigrees or populations. For SGS, genetic maps provide guidance in validating physical maps and sequence assembly, and SGS provides the most powerful tool for sequence polymorphism discovery.

4.3 Comparative Genome Analyses

Finally, one must emphasize the importance of comparative analyses. The NIH initiative of Mammalian Gene Collection (MGC) provides a precedent to direct focus towards this aspect. Representative mammal species from distinct taxonomic groups are all lined up in various sequencing pipelines, if not already sequenced. This is also being extended to other lower vertebrates and species in the root of chordates. Such comparative and systematic studies offer profound and broad information for not only genome annotation but also evolutionary studies on functional aspects of genes, gene families, and gene networks, thereby guiding molecular biologists to explore basic molecular mechanisms among all life forms. The next wave of genome sequencing will unquestionably go deeper and broader into taxa of the extant life forms, prioritized by economic and scientific interests. Comparative genomics offers a guidepost for targets of choice in genome sequencing, deviating from human-centric to species-focused.

5 Perspectives

Looking into the future of SGS, it is not only genomicists who have reason to be excited but also molecular biologists, and even field biologists in all disciplines. Genome sequencing is now well past its infancy and out of its crib. It is exploring new territories, checking out its skills, and learning all the time as it grows. Genomics has already broken out of its original definition and morphed into genome biology or systems biology without losing scale or momentum. What are some of the immediate challenges it has to face?

5.1 Large Genomes

Given the increasing requirements for sequence information, the need to tackle larger genomes is inevitable. The current records for finished genome projects on the basis of genome sizes are the human genome (among animal genomes) and rice (among plant genomes). Can WG-SGS strategy be applied to animal genomes larger than the human genome, or to plant genomes larger than that of rice? The answer is obviously yes but not without caveats. Genomes of different taxonomic groups vary quite significantly (Fig. 5). For instance, the genomes of mammals deviate very minimally from the mean size, about 3000 Mb, and are therefore suitable for simple WG-SGS. The next large plant genome to be sequenced may perhaps be the maize genome that is 2500 Mb in size. It is debatable, however, whether the wheat or barley genomes should be sequenced by the WG-SGS approach, because they pose an unprecedented challenge for sequence assembly on account of their repetitive contents (over 90%), their large sizes, and polyploid nature (in the case of wheat alone). Large insect and crustacean genomes, such as those of grasshoppers and shrimps, and large protist genomes

that have been largely untouched so far, should all be carefully evaluated before placed into a sequencing pipeline.

5.2 Genomes with High Repetitive Sequence Content

The repeat content, especially that of BDRs, varies widely among different taxonomic groups. Most notable are the plant genomes, some of which may have a repeat content as high as 95%. It is not a severe problem when the size of the target genome remains small, because the gene content can be put together easily and the cost is usually low. A balance between demands and costs is achievable within a threshold (say for genomes sized less than 3000 Mb). Large genomes in a size range of a few thousands of Mb have to be handled with great caution. Here, WG-SGC would not be suitable because of its high cost, rendering over 90% of the investment ineffective. Despite the fact that some of the gene content can be enriched experimentally by different methods (such as taking advantage of differential methylation between the gene and repeat contents among plant genomes), the goal of a dedicated genome project is to acquire a complete map of all its genes. In this regard, prioritization becomes a key for acquiring other resources (4) that are of great assistance in sequence assemblies and analyses over a relative prolonged period of time, in comparison with an ordinary genome project.

5.3 Polyploidy: Ancient and New

Polyploidy is very common among the extant species, some of it being ancient (formed naturally), and some recent (formed either naturally or artificially). A straightforward consideration for sequencing targets is to choose a diploid species (preferably the wild counterpart or the ancestor species) rather than a polyploid one, especially in the cases of crop species. However, in most cases, the preference is for the crop species to be sequenced directly first. In an ideal situation, the wild counterpart, the diploid species that gave rise to the modern polyploid crop, and the crop itself should all be sequenced in series. When there is no option, the genome of palepolyploid species should be evaluated first by physical mapping or sequence sampling for sequence divergence and feasibility of whole-genome assembly before a WG-SGS project is launched.

5.4 Mixed and Meta Genomes

In theory, when a mixture of multiple genomes is to be sequenced, it can be regarded as one organism with multiple chromosomes, perhaps in different ratios. For instance, genomes of a microbial community indigenous to a certain habitat are often referred to as *metagenomes*; examples of such habitats are the oral cavity, portions of a ruminant stomach, and even drinking water. However, microbes residing in the same environment are not guaranteed to propagate with the same speed and to respond to nutrient changes in similar ways. As a common characteristic under a defined circumstance, a microbial group is dominated by a limited number of species and contaminated by a large number of minor ones. Therefore, in an SGS project that utilizes DNA extracted from a meta-organism, genomes of the dominant species would be easily assembled, whereas those of the minor ones would have little chance of reaching full coverage. Unless novel strategies and techniques are

developed, such an endeavor provides only a survey of the metagenome and complete sequences of its few dominant members.

Acknowledgment

We apologize to our readers and colleagues for having only a limited number of citations from a recent explosion of genomic literature due to space limits. We would like to thank Ms. Wei Gong and Jing Wang for their valuable assistance in preparing the figures and tables, and Mr. Xin Zhang for proofreading the manuscript. The authors are supported by grants from National Natural Science Foundation (No. 30270748), Ministry of Science and Technology (No. 2002AA229021, 863-306-ZD11-04-1) and Chinese Academy of Sciences (KSCX2-SW-223).

Keywords

Agonist
Any chemical or physical signal that interacts with a specific receptor resulting in receptor activation. Agonists can be subdivided into partial agonists and full agonists depending upon the degree to which they activate the receptor, and the intrinsic, constitutive activity of a receptor can be suppressed by an inverse agonist.

Antagonist
Any chemical signal that interacts with a specific receptor, but neither activates the receptor nor suppresses the intrinsic activity of the receptor. These properties enable an antagonist to block the effects on an agonist or inverse agonist by competing for the receptor binding site.

Effector
A protein whose activity is directly regulated by an activated heterotrimeric G protein.

Heptahelical (7TM) Receptor
Integral membrane proteins that have seven amphipathic helices, and function as receptors for specific ligands. Agonist-mediated activation of heptahelical receptors results in the activation of specific heterotrimeric G proteins.

Heterotrimeric G Protein
A protein consisting of three different subunits referred to as α, β, and γ. The α-subunit has a guanine nucleotide binding site, and intrinsic GTPase activity. Agonist-occupied heptahelical receptors activate heterotrimeric G proteins by facilitating the dissociation of tightly bound GDP, allowing GTP to bind in its place.

Ligand
Any chemical or physical signal that interacts with a specific receptor. This includes full and partial agonists, antagonists, and inverse agonists.

Signal Transduction
A sequential series of biochemical reactions initiated by an environmental stimulus that interacts with a specific receptor located inside a cell or on the cell's surface.

G protein-mediated signal transduction pathways are involved in the responses of organisms and their constituent cells to a wide variety of stimuli. These stimuli include ions, light, gustants, odorants, small peptides, proteins, hormones, neurotransmitters, and lipids. The nature of the response can be equally diverse, varying from changes in gene transcription to altered ion channel kinetics. These pathways are utilized by nearly every species from yeast and fungi to mammals and higher plants. Heptahelical receptors, heterotrimeric guanine nucleotide binding proteins (G proteins) and their proximal downstream effectors constitute the core components of these ubiquitous signaling pathways. Signal transduction is usually initiated when an agonist binds to a selected heptahelical receptor, which in turn activates its cognate G protein. When activated, G proteins are able to regulate the activity of specific effectors such as adenylyl cyclase and ion channels. In addition to the core components, many accessory proteins are involved in the regulation of G protein–mediated signal transduction. Now the challenge lies in elucidating how these pathways with their many constituent components are organized within the cell. G protein–mediated signal transduction pathways are arguably the single most important class of targets for pharmaceuticals. By and large the drugs used for the therapeutic treatment of diseases involving G protein–mediated signaling are ligands that bind to the receptors for these pathways. Although receptor binding sites remain an important target for the development of new drugs, a thorough understanding of the organizational structure of G protein–signaling pathways is likely to reveal additional drug targets that may have therapeutic advantages over those that act as either agonists or antagonists for the receptors themselves.

1 Overview of G Protein–mediated Signal Transduction

Signal transduction refers to the biochemical events involved in the response of a cell to environmental cues. These messages, known as agonists, can take a variety of physical or chemical forms. They initiate their effects by interacting with specific receptor proteins on the cell surface, or in some cases, inside the cell. Receptors fall into four categories: (1) steroid hormone receptors that bind testosterone, estrogen, and other derivatives of cholesterol; (2) receptors that possess an intrinsic enzymatic activity such as receptor tyrosine kinases that respond to agonists such as growth factors and insulin; (3) receptors with an intrinsic ion channel activity such as nicotinic acetylcholine receptors; and (4) receptors that activate heterotrimeric guanine nucleotide binding proteins (G proteins). The latter category accounts for the large majority of receptors. In mammals there are approximately 1500 receptors that activate G proteins of which approximately two-thirds are odorant receptors associated with the sense of smell. A common feature of these receptors is that they have seven amphipathic helices arranged so that each helix fully traverses the membrane in which the receptor is embedded. This topography has given rise to the terms heptahelical receptor or seven transmembrane (7TM) receptor. Agonists for approximately 200 7TM receptors have been identified leaving the majority of 7TM receptors on a list of ''orphan'' receptors to await the discovery of their agonists.

G proteins that are activated by 7TM receptors are composed of three different subunits referred to as $G\alpha$, $G\beta$, and $G\gamma$. Yeasts have only one of each G protein subunit, while mammals express dozens of different G protein subunit combinations. The α-subunit contains the guanine nucleotide binding site, and in the unactivated G protein, GDP is bound to $G\alpha$. When an agonist binds to its 7TM receptor, it facilitates the dissociation of GDP, allowing GTP to bind in its place. This activates the G protein, which in turn regulates the activity of so-called effector proteins. The intrinsic GTPase activity of $G\alpha$ returns the G protein to its inactive state. As an enzyme, $G\alpha$ is a relatively slow catalyst, and in some cases catalysis can be accelerated by accessory proteins known as regulators of G protein–signaling (RGS) proteins. This scenario represents the rule and the requisite exceptions are: (1) 7TM receptors can mediate signal transduction without activating G proteins (hence, our choice of the term heptahelical receptors or 7TM receptors rather than the commonly used acronym GPCR for G protein–coupled receptors); (2) G proteins can be activated by proteins other than 7TM receptors; and (3) signal transduction involving mitogen-activated protein kinase cascades that are normally regulated by receptor tyrosine kinases can also be regulated by 7TM receptors and G proteins.

2 Historical Background

During the first few decades of the twentieth century it was discovered that cells react to extracellular chemical substances that we now call hormones and neurotransmitters. The concept of a ''receptor'' for these environmental messages arose in order to account for the ability of cells to discriminate between them, and respond specifically to them. By mid century, the

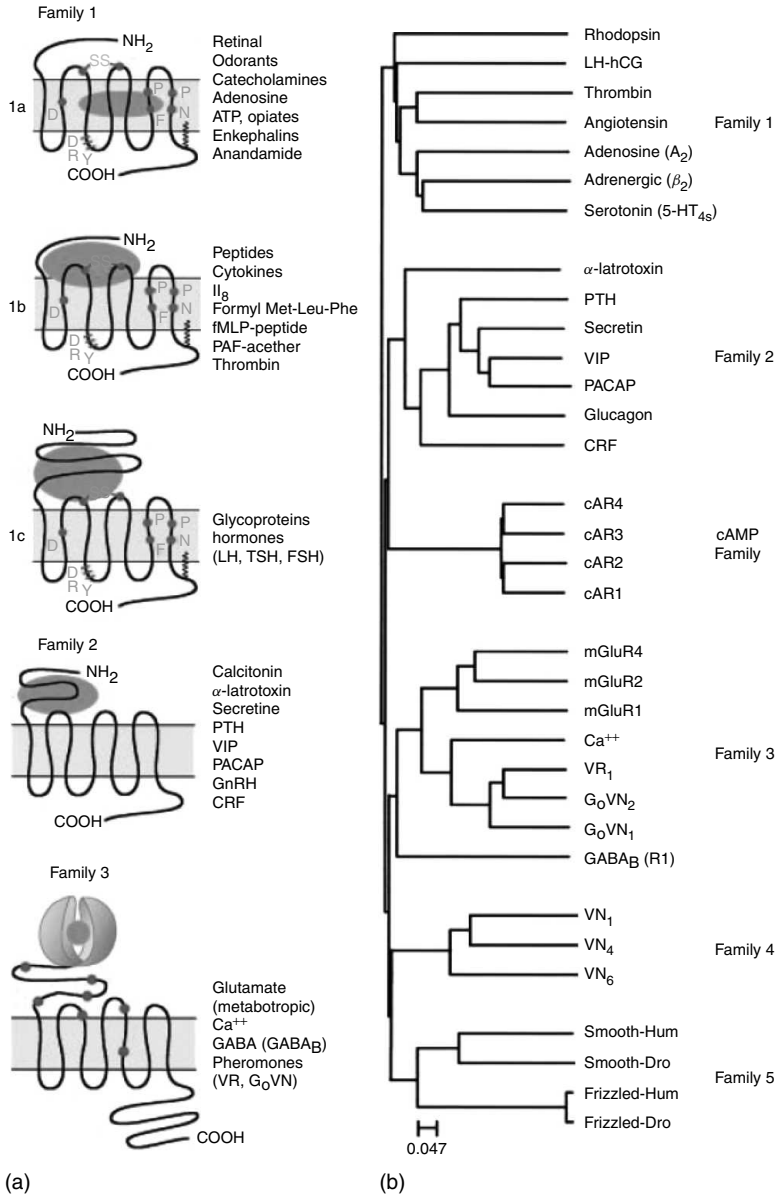
idea that hormones and neurotransmitters interacted with specialized receptors in the plasma membrane, and subsequently regulated the activity of ''effectors'' within the cell, was a prevalent hypothesis despite the fact that none of the cellular components involved in the process had been definitively identified. In the late 1950s, Sutherland and Rall discovered that bathing liver cells with a solution of epinephrine or glucagon lead to the production of adenosine 3′, 5′ monophosphate (cAMP) inside the cell. This observation provided evidence that information in the form of environmental cues could be converted by the cell into an intracellular ''second messenger.'' It was not apparent whether the enzyme responsible for cAMP synthesis, adenylyl cyclase (AC) (previously known as adenyl or adenylate cyclase), was itself the receptor or if there was a separate receptor component. Experimental data eventually revealed that both receptor and effector functions did not reside on the same protein. This raised the question of how information flowed from receptor to effector or, in the words of Martin Rodbell, what the ''transducer'' process was. The discovery that hormone-mediated stimulation of adenylyl cyclase required guanine nucleotide, that a guanine nucleotide binding component could be separated from the component responsible for catalyzing cAMP synthesis, and that GTP is hydrolyzed during the process led to the conclusion that the transducer was actually a separate component of the pathway. The transducer was eventually purified from retina and liver. The fact that the transducer contained the guanine nucleotide binding site eventually led to its being called a ''G protein.'' The intrinsic GTPase activity of the α-subunit identified the G protein as a molecular switch that allowed the chain of events known as signal transduction to occur when GTP was bound to the G protein, and to shut it off when the GTP was hydrolyzed. Although 7TM receptors, G proteins, and effectors constitute the essential elements of G protein–mediated signaling pathways, many accessory proteins that are critical for the signal transduction process have been discovered and characterized.

3
Heptahelical Receptors

3.1
Structure of Heptahelical Receptors and Mechanistic Aspects of Activation

7TM receptors have seven amphipathic helices, and each helix traverses the cell membrane once. Biochemical evidence showed that the N terminus was on the extracellular side of the plasma membrane leaving the C terminus on the cytoplasm side. The segments connecting the transmembrane domains are commonly referred to as *extracellular* and *intracellular* loops. Many 7TM receptors have a disulfide bond that links the first and second extracellular loops and a fatty acyl moiety covalently bound to their C-terminal cytoplasmic domains. 7TM receptors can be divided into six families (Fig. 1). Structural diversity in the binding site of 7TM receptors enables them to recognize an amazing variety of ligands, but despite this fact all 7TM receptors must activate a heterotrimeric G protein for signal transmission to occur. A bundle of the seven transmembrane domains is the structural element that allows this diverse collection of ligand binding sites to convert agonist binding into conformational changes that are capable of activating the G protein.

Rhodopsin is the best-studied 7TM receptor, and the first and only 7TM receptor to be crystallized. The crystal structure of rhodopsin provided information about a 7TM receptor in its inactive state, thus revealing the arrangement of the transmembrane helices with respect to one another (Fig. 2). Although no crystal structure for the active conformation of the receptor exists, a variety of data have been



used to predict specific agonist-induced changes in the receptor's conformation. These changes include both rotations and displacements of the transmembrane helices relative to one another that carry through to the cytoplasmic domains of the receptor, thus enabling it to activate its cognate G protein.

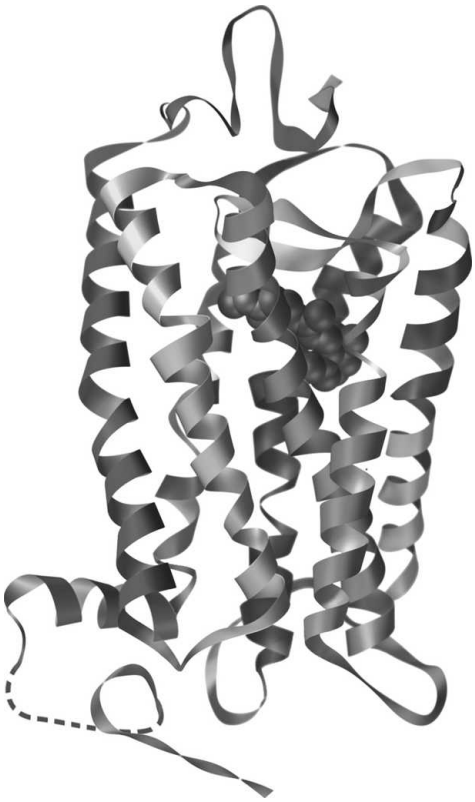


Fig. 2 Rhodopsin is depicted as a ribbon model based on the X-ray crystallographic structure of the receptor. Rhodopsin, like all heptahelical receptors, spans the cell membrane so that it is exposed to both the extracellular milieu and the cytoplasm. The model is oriented so that the extracellular and intracellular compartments are above and below the molecule, respectively. The 11-cis retinal that is isomerized to the trans-configuration when struck by a photon is shown as a space-filling model in purple. Each of the seven amphipathic helices is shown in a different color and rhodopsin has an additional short eighth helix near its C terminus that lies on the cytoplasmic surface of the cell membrane in the unactivated state of the receptor. (See color plate p. xxv.)

Fig. 1 7TM receptors can be divided into six families on the basis of sequence homology. (A) Three main families ((1, 2, and 3) can be easily recognized by comparing their amino acid sequences. Family 1 contains most 7TM receptors including odorant receptors. Family 1a contains receptors for small ligands and includes rhodopsin and β-adrenergic receptors. The binding site for this family is located within the seven transmembrane bundle. Family 1b contains receptors for peptides whose binding site includes the N-terminal, the extracellular loops and regions of the transmembrane domains near the extracellular surface. Family 1c receptors have a large extracellular N-terminal domain that together with extracellular loops 1 and 3 form the binding site for glycoprotein hormones. Family 2 7TM receptors have morphology similar to family 1c receptors, but they do not share sequence homology. Agonists for family 2 receptors include glucagon. Family 3 contains metabotropic glutamate receptors (mGluR) and γ-amino butyric acid receptors ($GABA_B$). (B) Family 4 receptors include pheromone receptors; family 5 contains ''frizzled'' and ''smoothened'' receptors that are involved in embryogenesis, and the family of cAMP receptors that have only been found in *D. discoideum*. Reprinted from *EMBO Journal*, Vol. 18, J. Bockaert and J. P. Pin, Molecular tinkering of G protein-coupled receptors: An evolutionary success, Pages 1723–1729, Copyright (1999), with permission from Macmillan Publishers Ltd.

3.2 Receptor Desensitization and Downregulation

Signaling by an activated 7TM receptor is rapidly attenuated by a process known as desensitization. Desensitization is initiated by sustained agonist-mediated activation of the receptor, which renders it susceptible to phosphorylation. The observation that rhodopsin was phosphorylated following activation by light led to the discovery of the first 7TM receptor kinase, which was dubbed rhodopsin kinase. Rhodopsin kinase is a member of a family of G protein–coupled receptor kinases (GRKs), and is now known as GRK1. Since its discovery, six additional GRKs (GRK2 through GRK7) have been identified. GRKs catalyze the phosphorylation of serine and threonine residues in the third intracellular loop and the C-terminal cytoplasmic domain of 7TM receptors. The efficacy with which GRK phosphorylates 7TM receptors can be modulated by other kinases. The consequence of GRK-mediated phosphorylation is that the 7TM receptor has an increased affinity for proteins known as arrestins. The prototypical member of this family, visual arrestin (originally known as 48-kD protein, and now called arrestin-1), is found in retinal rod cells. Two other family members, β-arrestin-1 and -2 (otherwise known as arrestin-2 and -3, respectively), are widely distributed, while the fourth member, cone arrestin, is found in retinal cone cells. The binding of arrestin to a GRK-phosphorylated 7TM receptor is believed to directly interfere with the receptors ability to activate its cognate G protein, attenuating signal transduction. Arrestins have also been labeled as ''scaffolding'' proteins (Sect. 6.3.1) because they bind many proteins in addition to phosphorylated 7TM receptors, and it is through these interactions that arrestin mediates the movement of phosphorylated 7TM receptors to microdomains on the cell surface known as coated pits. Associated with the cytoplasmic surface of coated pits are three proteins, the heavy chain of clathrin, adapter protein 2 (AP2) and N-ethylmaleimide-sensitive factor (NSF), which have been shown to bind β-arrestins. These proteins enable arrestin to drag 7TM receptors into the coated pit so that they can be taken into the cell by endocytosis. The extent to which different 7TM receptors are internalized varies depending upon their ability to engage the endocytotic machinery. In the process of endocytosis, coated pits become coated vesicles that deliver 7TM receptors to organelles called endosomes. Small GTP binding proteins including many Rab family members, ADP ribosylation factor 6, and GIT2 have also been implicated in the trafficking of 7TM receptors to endosomes. Heterotrimeric G proteins are also internalized after signaling, but the fate of the G protein is not known and little is known about the trafficking of effectors following signaling. The fate of the internalized 7TM receptors differs depending upon the type of receptor. Some receptors are resensitized by dephosphorylation and recycled back to the cell surface while others are degraded in a process known as downregulation. Factors governing which pathway a receptor takes remain to be elucidated.

3.3 Receptor-mediated Activation of Pathways that Do Not Involve G Proteins

7TM receptors are now recognized as being able to regulate biochemical pathways independently of heterotrimeric G protein

activation. Although 7TM receptors can activate mitogen-activated protein (MAP) kinase pathways by a G protein–dependent mechanism (Sect. 5.8), it is also clear that these receptors can do so by a G protein-independent mechanism. MAP kinase pathways are so named because of their involvement in the response of cells to mitogenic signals that typically act through receptor tyrosine kinases including epidermal growth factor (EGF) receptors or fibroblast growth factor receptors, among others. The cellular slime mold, *Dictoystelium discoideum*, has a number of 7TM receptors, but only one gene for a Gβ. Disruption of the gene for Gβ prevents activation of all known G protein–dependent effectors in Dictoystelium, but these Gβ null mutants retain the ability to activate MAP kinase pathways after 7TM receptor stimulation. 7TM receptor regulation of MAP kinase pathways also occurs in mammalian cells. The mechanism may involve events that are associated with receptor desensitization, including phosphorylation of the agonist-occupied 7TM receptor by GRK and arrestin binding, but the actual process of endocytosis (Sect. 3.2) is not a prerequisite for MAP kinase activation. In addition to MAP kinase pathways, other G protein–independent physiological responses to 7TM receptor activation have been identified, including alterations in gene transcription and ion fluxes across membranes.

4
G Proteins

4.1
Structure and Mechanistic Aspects of G Protein Activation

The crystal structure of a heterotrimeric protein revealed that Gα has two domains. One domain is replete with α-helices prompting it to be named the α-helical domain, and the other that contains the guanine nucleotide binding site has a structure similar to the small GTP binding protein Ras, thus it is called the Ras-like domain (Fig. 3). The N terminus of Gα subunits is covalently modified by the attachment of myristate, palmitate, or both. Myristate or palmitate is bound by an amide linkage to the N-terminal glycine residue (exposed after removal of the initiator methionine) while palmitate is attached by a thioester linkage to a cysteine near the N terminus.

Gβ has seven similar structural domains that are assembled so that they resemble a seven bladed propeller. The N terminus of Gβ extends beyond the propeller, and is intertwined with the N terminus of Gγ forming a coiled coil structure. The C terminus of Gγ is covalently modified by the attachment of an isoprenoid moiety (either a geranylgeranyl or farnesyl group). The N terminus of Gα, with its covalently bound fatty acyl chains lies close to the isoprenylated C terminus of Gγ and these hydrophobic moieties are important for anchoring the G protein to the cell membrane. The N terminus of Gα also makes contact with amino acid residues in the first blade of the Gβ propeller. In the unactivated G protein, one surface of the Gβ propeller makes additional contact with a region of Gα known as the "switch interface." The switch interface is so named because it contains regions called switches that change conformation when GTP or a GTP analog replaces GDP in the guanine nucleotide binding site of Gα. Activation of the G protein by an agonist-occupied 7TM receptor disrupts the interaction between Gβ and the switch interface of Gα allowing GDP to dissociate so that GTP can bind in its place. In the

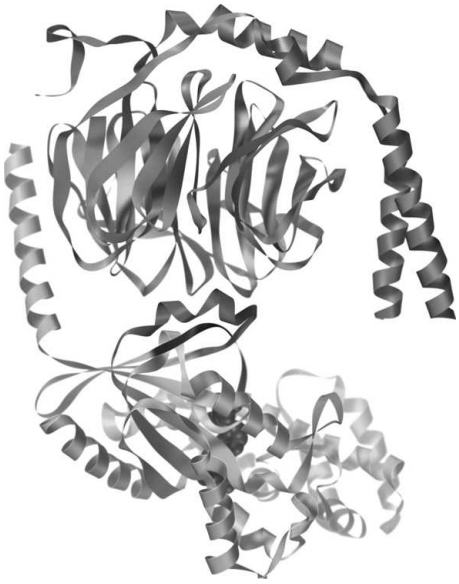

Fig. 3 The unactivated conformation of a heterotrimeric G protein is shown as a ribbon model with bound GDP depicted as a space-filling model (purple) within the Gα subunit. The model is based on the X-ray crystal structure of a protein consisting of a chimeric α-subunit composed predominantly of residues from Gα_t associated with the transducin G$\beta\gamma$ heterodimer (Gβ is shown in blue). The C terminus of Gγ (green) and the N terminus of Gα, which have covalently attached hydrophobic moieties that anchor the G protein to the membrane, lie close to each other at the upper left of the figure. Switches I, II, and III on Gα are shown in progressively lighter shades of red. (See color plate p. xxxii.)

GTP bound state, the conformation of the three switches are significantly altered, thereby preventing Gβ from binding to this surface of Gα. In this way, the G protein is held in an active conformation until GTP is hydrolyzed and the switches can return to their inactive conformations, thus allowing Gβ to again interact with the switch interface on Gα. GTP hydrolysis is a consequence of the intrinsic GTPase activity of Gα (EC 3.6.5.1). The catalytic rates for GTP hydrolysis by G proteins are characteristically slow for an enzyme, but they can be increased by accessory proteins known as *regulators of G protein signaling* or RGS proteins (Sect. 4.3).

There are 12 mammalian genes that code for Gγ subunits, five that code for Gβ subunits, and 16 that code for Gα subunits. The Gα subunits are grouped into four subfamilies (G_s, $G_{i/o}$, $G_{q/11}$, and $G_{12/13}$) on the basis of sequence homology (Table 1). The subtype of G protein responsible for regulating the activity of specific effectors can be found in Sect. 5.

4.2 G Protein Regulation that Does not Involve Heptahelical Receptors

Aside from 7TM receptors, there exists a diverse group of proteins that can interact directly with G proteins, and a number of them are capable of activating G proteins by various mechanisms. The first nonreceptor protein recognized as being able to activate a G protein was cholera toxin produced by the bacteria *Vibrio cholera*. Cholera toxin is an ADP-ribosyl transferase that covalently attaches the ADP-ribose moiety of NAD to an arginine residue (Arg^{201} of bovine Gα_s) in "switch I" of Gα_s. This covalent modification prevents G_s from hydrolyzing GTP once it is bound. As a consequence, G_s becomes irreversibly activated, with important consequences for the progression of the disease cholera. Another toxin, pertussis toxin, from the bacteria *Bordetella pertussis* is also an ADP-ribosyl transferase, but its substrate is a cysteine residue near the C terminus of G

Tab. 1 Heterotrimeric G proteins.

Name	***Gene***	***Expression***
α-Subunits		
$G\alpha_s$ class		
$G\alpha_s$	*Gnas*	Ubiquitous

γ_{10}	*Gng10*	Widely
γ_{11}	*Gng11*	Widely
γ_{12}	*Gng12*	Widely
γ_{13}	*Gng13*	Taste buds

The table lists heterotrimeric G protein subunits encoded by mammalian species together with their tissue distribution and the gene symbol. Gα subunits are divided into subclasses on the basis of sequence homology. Reprinted from *Progress in Biophysics and Molecular Biology*, Vol. 83, S. Offermanns, G-proteins as transducers in transmembrane signalling, Pages 101–130, Copyright (2003), with permission from Elsevier.

proteins that belong to the G_i subfamily. ADP ribosylation of G_i by pertussis toxin prevents it from being activated by a 7TM receptor. Mastoparan is a tetradecapeptide found in wasp venom that activates G_i by virtue of being a 7TM receptor mimetic. Analogs of mastoparan that activate G_s have also been prepared.

Receptor tyrosine kinases (*e.g.* growth factor receptors) can also use G proteins to regulate the activity of downstream effectors apparently without involving 7TM receptors. Among the receptor tyrosine kinases that fall into this category are platelet-derived growth factor receptors, insulin receptors, and insulin-like growth factor-1 receptors. Other non-7TM receptors have also been implicated in the activation of G proteins. These include erythropoietin receptors and a glycosylphosphatidylinositol-anchored receptor, CK14.

Three mammalian proteins designated AGS1, AGS2 and AGS3 (activators of G protein signaling) were identified by a screen designed to detect proteins that could activate G proteins. Despite the nomenclature, these three proteins are not homologs. AGS1 is identical to DexRas1, a member of the Ras superfamily. AGS1 has been shown to facilitate the binding of a GTP analog to G_i, accounting for its ability to activate G_i. AGS2 is identical to tctex1, the light chain of cytoplasmic motor protein dynein. AGS2 does not cause an exchange of guanine nucleotides but appears to disrupt the interaction between Gα and the G$\beta\gamma$ heterodimer, exposing epitopes on the latter that are capable of activating downstream effectors. AGS3 is a mouse protein with homologs in humans (LGN) and the fruit fly *Drosophila melanogaster* (Partner of Inscrutable or Pins). Pins is important for the asymmetric cell division in the *Drosophila* embryo. Although AGS2 and AGS3 were identified on the basis of their ability to activate G proteins in a genetic screen, it is not yet clear that they do so as part of their normal physiological function. However, the ability of AGS proteins to interact with G proteins is certain to be important *in vivo*. Other activators of G proteins include the microtubule protein tubulin, a protein found in the growth cones of neurons called GAP-43, a protein associated with familial Alzheimer's disease known as presenilin-1, G protein activator, and phosphatidylethanolamine-binding protein. Other proteins that do not activate G proteins, but are reported to regulate them include caveolin (Sect. 6.3.1), the signature proteins of lipid microdomains called *caveolae*.

4.3 Attenuation of G Protein Activity by Regulators of G Protein–signaling Proteins

The visual image that you perceive is a consequence of signal transduction mediated by the G protein G_t. The α-subunit of transducin (G_t) hydrolyzes GTP, but the rate of catalysis is extremely slow. The half-life for GTP bound to purified G_t is approximately 15 s, but when you close your eyes, the image disappears without a perceptible delay. How can signal transduction be terminated so quickly in the intact cell if G proteins turn themselves off at such a slow rate? This question prompted the search for GTPase activating proteins (GAPs) that could accelerate the rate of GTP hydrolysis by G proteins, and eventually led to the discovery of a group of proteins known as RGS proteins. RGS proteins have a conserved sequence consisting of approximately 130 amino acids

that is known as the RGS box, and they have been divided into subfamilies on the basis of the homology within this domain. There are at least 20 mammalian RGS proteins, and many of them act as GAPs for the $G_{i/o}$, and $G_{q/11}$ subfamilies of G proteins. Notably, no RGS protein capable of acting as a GAP for G_s has been identified, and not all RGS proteins have GAP activity. RGS proteins that act as GAPs are capable of accelerating the GTPase activity of G proteins by as much as 1000-fold, but they do not directly participate in the hydrolysis of GTP. Phosphorylation of G proteins can alter their susceptibility to the GAP activity of RGS proteins. Several RGS isoforms have palmitate covalently attached to cysteine residues, which provide a hydrophobic moiety that may be important for their association with membranes. Many RGS proteins also have sequences flanking their RGS box that contain various domains important for intermolecular interactions with proteins in addition to $G\alpha$. For example, members of the RGS9 subfamily have a 64 amino acid domain that resembles the C terminus of $G\gamma$ subunits referred to as a $G\gamma$-like (GGL) domain. The GGL domain is responsible for binding to the brain-specific $G\beta_5$ subunit, and *in vivo*, $G\beta_5$ evidently exists as a complex with RGS9. There is evidence that individual RGS proteins regulate selected signaling pathways, though relatively little is known about this aspect of RGS proteins. Two effector proteins, phospholipase $C\beta$ (Sect. 5.4) and RhoGEFs (Sect. 5.7), have been shown to serve as RGS proteins for the respective G proteins which activate them, G_q and $G_{12/13}$, and the effector, cGMP phosphodiesterase (PDE)(Sect. 5.1), greatly enhance the ability of RGS9 to serve as a GAP for the G protein G_t.

5 Effectors

5.1 cGMP Phosphodiesterase

A mechanism for detecting light is one of the indispensable elements needed for vision. In mammals, this function is performed by specialized cells called rods and cones that are located in the retina. The process of detecting light is referred to as phototransduction to reflect the fact that it is a signal transduction process, and it requires the participation of a heterotrimeric G protein. Because the G protein responsible for mediating phototransduction was one of the first proteins to be recognized as fulfilling the role of the ''transducer'' that was proposed by Martin Rodbell, it came to be called transducin (abbreviated here as G_t). The 7TM receptor responsible for activating G_t is rhodopsin, and the effector that is regulated by G_t is cyclic GMP phosphodiesterase (PDE). The process of phototransduction, including information about the structure, function, and regulation of PDE is discussed in greater detail in Sect. 7.2.

5.2 Adenylyl Cyclase

Adrenergic receptors are among the 7TM receptors that regulate the activity of AC. The importance of adrenergic signaling in cardiovascular function and disease has made AC one of the most intensively studied G protein–regulated effectors. The activity of AC can either be increased or decreased depending upon the G protein–mediated pathway that is activated. 7TM receptors like the prototypical β_2-adrenergic receptor activate G_s leading to stimulation of AC, while 7TM receptors

such as the α_2-adrenergic receptors activate G_i causing inhibition of AC. There are nine different mammalian isoforms of AC and they are all activated by G_s and inhibited by G_i. The ability of G_s to activate ACs was initially attributed entirely to determinants on the α-subunit. However, it is apparent that the activation of some ACs, specifically type II and type IV, also require the presence of the $G\beta\gamma$ heterodimer.

AC is an integral membrane protein with two putative membrane-spanning domains, called M1 and M2. Each of these domains is predicted to possess six membrane-spanning helices. M1 and M2 are connected by a large intracellular domain called C1, and AC has a large intracellular C-terminal domain referred to as C2. Together C1 and C2 form the catalytic domain that is regulated by G proteins. In addition to being regulated by G proteins, ACs are activated by the diterpene forskolin from the root of the plant *Coleus forskohlii*, and inhibited by certain purinergic compounds such as adenosine that bind to the so-called P-site on ACs. Some isoforms of AC, notably types I and VIII, are activated by Ca^{2+}-calmodulin.

When activated, AC catalyzes the production of cAMP, and increased intracellular levels of this second messenger cause a concomitant increase in protein kinase A (PKA) activity. Subsequently, activated PKA phosphorylates many protein substrates, including 7TM receptors, thereby regulating their activity. For each step in this cascade, there is an opposing reaction that enables the pendulum to swing both ways. Desensitization occurs when the active conformation of the receptor is phosphorylated by a GRK leading to arrestin binding and a consequent attenuation of the receptor's ability to activate its cognate G protein (Sect. 3.2). The intracellular concentration of cAMP is reduced when it is hydrolyzed by PDE, and the products of reactions catalyzed by PKA become the substrates for dephosphorylation by protein phosphatases.

5.3 Phosphoinositide 3-Kinase

Phosphoinositide 3-kinases (PI3Ks) phosphorylate the 3′-OH on the inositol ring of phosphoinositides. They are inhibited by the drug LY294002 and by the fungal metabolite wortmannin, and can be categorized as class I, II, or III. Class I PI3Ks is further subdivided into classes IA and IB. PI3Kα, β, and δ constitute class IA and their respective p110α, β, and δ catalytic subunits can bind any of the seven p85 adaptor subunits that range in molecular weight from 50 to 85 kDa. PI3Kγ is the only member of class IB and is most abundant in leukocytes in which it is located on or juxtaposed to the plasma membrane. PI3Kγ differs from its class IA counterparts in that its p110γ catalytic subunit cannot bind to p85 adaptor subunits. Instead, p110γ binds to an adaptor subunit designated p101 that has no known homologs. As with certain isoforms of AC (Sect. 5.2), there is evidence for roles of both Gα and G$\beta\gamma$ in the activation of classes IA and IB PI3Ks. PI3Ks in turn regulate the activity of many proteins including protein kinase B (PKB/Akt), protein kinase Cγ, c-Jun N-terminal kinase (JNK) and L type Ca^{2+} channels.

5.4 Phospholipase Cβ

There are 11 different isoforms of phospholipase C (PLC) and they are subdivided into four groups designated β, γ,

δ, and ε. All PLC isoforms consist of a single polypeptide chain that catalyzes the hydrolysis of phosphotidylinositol 4,5-bisphosphate (PIP_2) producing inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 triggers an increase in intracellular Ca^{2+}, and together, DAG and Ca^{2+} activate "classical" protein kinase C (PKC) isoforms, or DAG by itself can activate "novel" PKC isoforms. Many PKC substrates have been identified and phosphorylation by PKC leads to a variety of physiological consequences. Four of the PLC isoforms belong to the β-subfamily (PLCβ1 through PLCβ4), and each PLCβ isoform can be activated by 7TM receptors that couple to G proteins belonging to the $G_{q/11}$ subfamily. PLCβ1 is a GAP for $G_q\alpha$ (Sect. 4.3), which binds to the α-subunit with a K_D of about 2 nM, and increases the rate of GTP hydrolysis by approximately 1000-fold.

5.5
G Protein–coupled Inwardly Rectifying Potassium (Kir3) Channels

Inwardly rectifying K^+ channels belonging to the Kir3 family are critical for the regulation of resting membrane potential in excitable and nonexcitable cells and they are regulated by 7TM receptors. There are four types of Kir3 subunits designated Kir3.1 through Kir3.4. These are assembled as homo- or heterotetramers, though not all combinations produce functional ion channels. Kir3 subunits have two transmembrane domains, and both the N and C terminus are on the cytoplasmic side of the cell membrane. Direct regulation of Kir3 by G proteins is a membrane-delimited event that occurs on a millisecond timescale, and it is mediated by determinants on the G$\beta\gamma$ heterodimer rather that the Gα subunit. A number of studies have demonstrated that little specificity exists *in vitro* when G$\beta\gamma$ heterodimers of different subtype composition are used to regulate effectors such as Kir3. Although Kir3 can be activated by G$\beta\gamma$ alone, the channel also binds Gα. The N-terminal domain of the Kir3 channels binds to both Gα and G$\beta\gamma$, and the channel's C-terminal domain has additional binding sites for G$\beta\gamma$. Kir3 channels are regulated by the G_i subfamily of G proteins, and pertussis toxin (Sect. 4.2) blocks the 7TM receptor-mediated opening of Kir3 channels. 7TM receptors that activate both G_s and G_q can also regulate Kir3 channels. Regulation by receptors that activate G_s may be direct or it may be a consequence of PKA activation brought about by the G_s-mediated stimulation of AC (Sect. 5.2). PIP_2 is important for Kir3 channel activity, and 7TM receptors that activate PLC (Sect. 5.4) via a G_q-mediated mechanism can attenuate channel opening by reducing the concentrations of PIP_2 in the membrane.

5.6
N and P/Q Type Calcium Channels

Voltage-gated Ca^{2+} channels are composed of five different subunits (α_1, α_2, β, γ, and δ) and are subdivided into five different types (L, N, P/Q, R, and T). The α_1 subunit has four similar hydrophobic domains (I–IV) each consisting of six transmembrane helices. Domains I through IV are connected by intracellular loops, and the α_1 subunit has a relatively large intracellular C-terminal domain. The Ca^{2+} channel β-subunit interacts with the intracellular loop between domains I and II of the α_1 subunit as well as the N and C terminus. The β-subunit is important for transport of the channel from the endoplasmic reticulum (ER) to the plasma

membrane, and for both the kinetic and voltage-dependant properties of the channel. N and P/Q type Ca^{2+} channels are also directly inhibited by G_o which antagonize the effects of the Ca^{2+} channel β-subunit. It is the $G\beta\gamma$ heterodimer that is responsible for regulating the activity of the channel, though $G\alpha$ has also been reported to bind to the α_1 channel subunit. There is evidence that the N and C termini of α_1 subunit is involved in Ca^{2+} channel regulation by $G\beta\gamma$, and $G\beta\gamma$ binds to the intracellular loop between domains I and II of α_1. Though this latter interaction does not preclude the binding of the Ca^{2+} channel β-subunit to α_1, it does appear to alter the orientation between the two channel subunits providing a possible clue regarding the mechanism of G protein–mediated regulation of Ca^{2+} channels. Apparently there are also differences in the ability of $G\beta\gamma$ to regulate Ca^{2+} channels depending upon the subtype of the channel β-subunit, and the subtype of $G\beta$ that is involved in regulating the channel.

The α_1 subunit of Ca^{2+} channels can be phosphorylated by PKC (Sect. 5.4). PKC-mediated phosphorylation of the loop between domains I and II of the α_1 subunit relieves the $G\beta\gamma$-induced inhibition of N type Ca^{2+} channels. The ability of PKC to target the α_1 subunit may involve interaction with determinants on the $G\beta\gamma$ that is bound to the channel subunit. Thus, there are two modes by which G proteins are involved in regulating N type Ca^{2+} channels; a direct inhibition of the channel by activated G_o, and an indirect mechanism for alleviating the $G\beta\gamma$-mediated inhibition through 7TM receptors that can activate PKC. Ca^{2+} channels that are not directly regulated by $G\beta\gamma$ subunits (*i.e.* L type) are, however, susceptible to indirect regulation by G protein–mediated pathways. The α_1 subunits of L type Ca^{2+} channels as well as the channel β-subunit are phosphorylated by PKA (Sect. 5.2) resulting in increased channel activity. A protein known as A kinase anchoring protein (AKAP – see Sect. 6.3.1) facilitates modulation of channel activity by PKA. Furthermore, a peptide designed to ablate the binding of PKA to AKAP inhibits the regulation of L type Ca^{2+} channel by 7TM receptor-mediated activation of PKA. These data indicate that localization of PKA by virtue of being associated with other proteins is important for Ca^{2+} channel regulation by the kinase.

5.7 RhoGEFs

Rho is a member of a family of ''small'' monomeric G proteins that is involved in regulating the architecture of the actin cytoskeleton, and consequently is important for cell motility. Aberrant activation of pathways regulated by Rho can also convert cells from a normal to a transformed phenotype. Rho has a guanine nucleotide binding site, and it is activated when GTP is bound. Whether GDP or GTP is bound to Rho is controlled by guanine nucleotide exchange factors (RhoGEFs) that promote the exchange of GDP for GTP, GTPase activating proteins (GAPs) that accelerate the intrinsic GTPase activity of Rho, and guanine nucleotide dissociation inhibitors (RhoGDIs) that inhibit the dissociation of GDP. The motif in RhoGEFs responsible for catalyzing nucleotide exchange is the Dbl homology (DH) domain. Three RhoGEFs, p115RhoGEF, PDZ-RhoGEF, and leukemia-associated RhoGEF (LARG), are regulated by heterotrimeric G proteins of the $G_{12/13}$ family. Each of these RhoGEFs contains an RGS domain (Sect. 4.3) that serves both as a site for the interaction of $G_{12/13}$ with the RhoGEFs,

and to terminate activation by $G_{12/13}$. The mechanism by which $G_{12/13}$ activates the GEF activity of RhoGEF has not been established. At present the favored hypothesis is that inhibition of the GEF activity is relieved when the activated $G_{12/13}$ interacts with the RGS domain of RhoGEF, allowing the DH domain to catalyze nucleotide exchange on Rho. Rho can also be activated by 7TM receptors that activate G_q, but RGS containing RhoGEFs are not involved in these pathways.

5.8 Mitogen-activated Protein (MAP) Kinases

Receptors for mitogenic substances such as growth factors (*e.g.* EGF, platelet-derived growth factor, nerve growth factor, etc.) have intrinsic tyrosine kinase activity, and are referred to as receptor tyrosine kinases (RTK). RTK function as homodimers composed of subunits that have a single transmembrane domain. Activation occurs when an agonist bound to one RTK subunit causes phosphorylation of tyrosine residues in the cytoplasmic domains of its dimeric partner (trans-autophosphorylation). Phosphotyrosine residues in RTK provide binding sites for proteins with SH2 domains, and this facilitates the assembly of a protein complex that initiates the phosphorylation of numerous proteins including a 42-kDa protein originally designated pp42. The discovery that pp42 was itself a serine/threonine kinase resulted in its being renamed mitogen-activated protein (MAP) kinase. This particular MAP kinase is one member of a family of proteins that now include about 20 different mammalian homologs. Despite the fact that many members of this family play roles in the response of eukaryotic cells to environmental factors other than mitogens, they are all referred to as mitogen-activated protein kinases. MAP kinases can be divided into subfamilies, and the subfamily known as extracellular-signal regulated kinases (ERK) claims ERK1, alias pp42, as a member. MAP kinases are activated when both threonine and tyrosine in a T-X-Y sequence are phosphorylated by a kinase designated MAP kinase kinase (MAPKK). The MAPKK is activated when it is phosphorylated by a MAP kinase kinase kinase (MAPKKK). Together a MAPKKK, a MAPKK, and a MAP kinase constitute a module, and as a rule appear to be held in physical proximity by a scaffolding protein (Sect. 6.3.1).

In addition to regulation by RTKs, MAP kinase modules can be activated by agonists for 7TM receptors. One of the most extensively studied G protein–mediated signaling pathways activates a MAP kinase module in yeast that regulates their mating behavior. Mutations in numerous genes render yeast sterile (*i.e.* unable to mate), and many of these gene products bear the designation "Ste" to reflect this fact. Peptide pheromones secreted by yeast bind to 7TM receptors (Ste2 and Ste3) triggering the fusion of two compatible haploid individuals. These pheromone receptors are coupled to the single G protein expressed in yeast. The G protein in turn interacts directly with several proteins, including a kinase (Ste20) belonging to the family of p21-activated kinases (PAKs), and two proteins, Far1 and Ste5, that serve as scaffolds for the assembly of protein complexes. In addition to interacting with the yeast G protein, Ste20, Far1 and Ste5 interact with each other indirectly through their associations with other proteins, creating a complex network of protein–protein interactions. The extensive interactions between the yeast G protein and downstream components make it difficult to point to a single protein as the effector in this

pathway, but the result is the activation of Ste20 and a MAP kinase module consisting of Ste 11 (MAPKKK), Ste7 (MAPKK), and Fus3/Kss1 (MAP kinases).

In higher eukaryotes, Raf (*i.e.* cRaf-1 or B-Raf), MEK (*i.e.* MEK1 or MEK2), and ERK (*i.e.* ERK1 or ERK2) are the respective MAPKKK, MAPKK, and MAP kinase of a module that is regulated by both 7TM receptors and RTK. Activation by RTK involves the agonist-induced trans-autophosphorylation described earlier, which initiates a cascade of events that leads to ERK activation (Fig. 4). Phosphotyrosine residues on the RTK allow the receptor to bind proteins with SH2 domains such as Shc (Src homology/collagen). The phosphorylation of tyrosine residues in Shc provides a binding site for the SH2 domain of the protein Grb2 (growth factor-receptor bound 2), which brings with it a protein called *Sos (son of sevenless)*. Sos is a guanine nucleotide exchange factor for the small G protein Ras, and the GEF activity of Sos activates Ras by facilitating the exchange of bound GDP for GTP. Activated Ras in turn activates Raf leading to ERK activation. The regulation of ERK by 7TM receptors is less well defined, and apparently can occur via several distinct pathways depending upon the particular 7TM receptor and the type of cell. It is possible for 7TM receptors to regulate MAP kinase without involving G proteins (Sect. 3.3), though the focus here will be on the pathways that do involve G proteins.

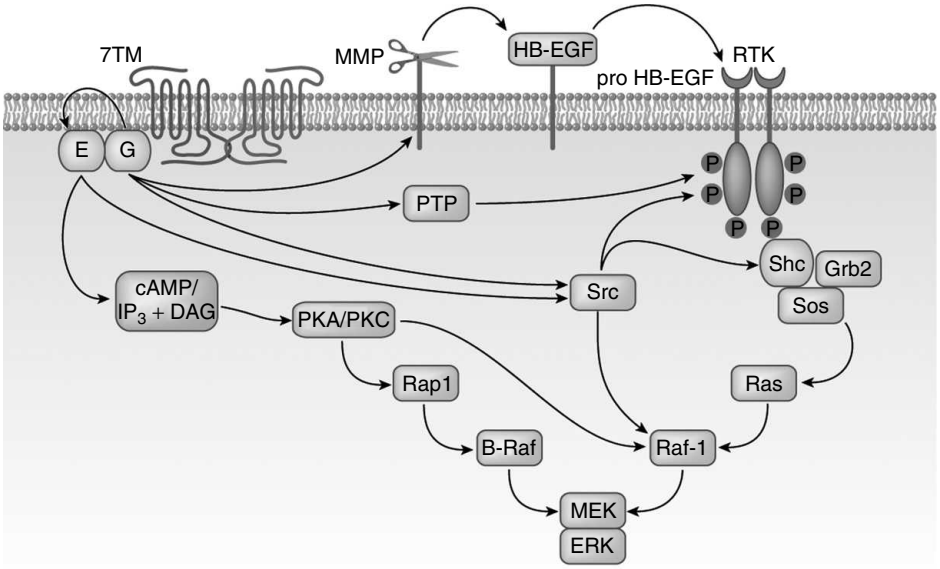

Fig. 4 Pathways leading to the activation of MAP kinase are summarized (see Sect. 5.8 for an explanation). The 7TM receptor is shown as a dimer. cAMP, IP_3, and DAG are second messengers; E, effector; ERK, MAP kinase; G, heterotrimeric G protein; Grb2 and Shc, adaptor proteins; HB-EGF, heparin binding epidermal growth factor; MEK, MAP kinase kinase; MMP, matrix metalloprotease; PKA, protein kinase A; PKC, protein kinase C; PTP, protein tyrosine phosphotase; Raf-1 and B-Raf, MAP kinase kinase kinases; Rap 1 and Ras, small monomeric GTP binding proteins; RTK, receptor tyrosine kinases; Src, tyrosine kinases; Sos, guanine nucleotide exchange factor for Ras.

A simplified scheme for many of these pathways is shown in Fig. 4.

If the regulation of MAP kinase activity by a 7TM receptor requires the participation of an RTK, this process is known as "transactivation." For example, activation of a 7TM receptor may result in the production of an RTK agonist leading to the conventional agonist-mediated regulation of ERK. This involves the activation of a matrix metalloprotease (MMP). There may be more than one pathway by which 7TM receptors activate MMPs, and the intermediate steps have not been elucidated. Once activated, the protease cleaves proHB-EGF to liberate heparin binding EGF (HB-EGF) from the extracellular surface. HB-EGF is an EGF receptor agonist, and binding to its receptor initiates the cascade of events resulting in ERK activation. Alternatively, transactivation can occur by an agonist-independent activation of the RTK. One likely mechanism involves a 7TM receptor-mediated inhibition of protein tyrosine phosphotase (PTP) that effectively favors the activated state of the RTK by preventing dephosphorylation of phosphotyrosine residues in the receptor.

7TM receptors also regulate MAP kinase activity through pathways that involve the Src family of nonreceptor tyrosine kinases. Regulation has been tied to 7TM receptors that activate G_s, G_i, and G_q, and may or may not involve second messenger-dependent events. Phosphorylation of Src increases its kinase activity, and activated Src can phosphorylate Raf, RTK, and Shc. Src-mediated phosphorylation of RTK and Shc enable them to initiate the Ras-dependent activation of Raf, thus contributing to ERK activation, and although GTP-liganded Ras is required for Raf activation, Src-mediated phosphorylation of Raf also contributes to Raf activation.

6
The Organization of G Protein-mediated Signal Transduction Systems

6.1
The Classical Model of G Protein–mediated Signal Transduction

Many of the components involved in G protein–mediated signal transductions are integral or peripheral membrane proteins; thus, the initial steps in signal transduction are membrane-delimited events. Heterotrimeric G proteins were the first of the signaling proteins to be purified, and their activation in solution leads to the dissociation $G\alpha$ from the $G\beta\gamma$ heterodimer. The model that emerged depicted signaling proteins as moving about independently of one another in the membrane with signal transduction being propagated by a series of transient bimolecular interactions. The process is initiated when an agonist binds to its 7TM receptor causing it to adopt an active conformation that can then bind its cognate heterotrimeric G protein, forming a "ternary complex." The activated 7TM receptor enables GDP to dissociate from $G\alpha$ allowing GTP to bind in its place. This leads to the dissociation of the G protein subunits from each other, and from their 7TM receptor. Subsequently, $G\alpha$ and $G\beta\gamma$, either independently or in concert with one another, regulate the activity of specific effector proteins that they encounter as they move about in the plane of the membrane. When the GTP bound to $G\alpha$ is hydrolyzed, the subunit becomes inactive and its affinity for $G\beta\gamma$ is increased allowing the formation of an inactive heterotrimeric G protein, thus completing the cycle.

When the model for the propagation of signals mediated by G proteins were first being developed, the number of different

components known to be involved in the process was relatively small. By 1980, two G proteins (G_t and G_s), a few receptors, and two effectors (PDE and AC) had been identified, and the concept that G protein–mediated signal transduction was propagated as the result of transient bimolecular interactions provided a satisfactory explanation of the mechanics of signal transduction. Subsequently, there was an explosion in the discovery of G protein–signaling components so that now there are hundreds of 7TM receptors, dozens of different G protein subunits, and numerous effector proteins. Along with an appreciation for the large number of components involved in G protein–mediated signal transduction has come the knowledge that individual cells contained multiple G protein–mediated signaling pathways. This fact is exemplified by the rat portal vein myocyte, which has at least 11 different receptors capable of activating G proteins, 7 different $G\alpha$ subunits, 5 different $G\beta$ subunits, 8 different $G\gamma$ subunits, and 6 different effectors whose activities are regulated by G proteins.

Despite the presence of dozens of different signaling components within a single cell, G protein-mediated signal transduction generally displays a high degree of fidelity that cannot be explained by the classical model. For example, the subtype composition of a G protein (*i.e.* the subtype of $G\alpha$, $G\beta$, and $G\gamma$) determines what 7TM receptor a heterotrimeric G protein couples to. It is also known that individually, $G\alpha$ and $G\beta\gamma$ have a low affinity for 7TM receptors; consequently, they must be associated as a heterotrimer before interacting with their cognate receptor. If G protein subunits dissociate from each other and from their receptor when activated, then subunit reassociation must occur before the G protein can interact with the receptor again. $G\alpha$ subunits have comparable affinities for $G\beta\gamma$ heterodimers of any subtype composition. Since most cells have $G\beta\gamma$ heterodimers in many different subtype combinations, it is unlikely that G protein subunits would reassociate to produce a heterotrimer with the same subunit composition as that originally activated by the receptor. This would produce a situation within the cell in which the pool of G protein capable of coupling to a given 7TM receptor would be in constant flux.

Another enigma associated with the classical model involves the activation of effectors by G proteins. Although it was originally thought that only $G\alpha$ subunits were responsible for regulating the activity of effectors, it later became apparent that $G\beta\gamma$ heterodimers were also involved in propagating signals. The first effector recognized as being regulated by $G\beta\gamma$ was the inwardly rectifying potassium channel. Subsequently, it was discovered that a number of other effectors were also regulated by $G\beta\gamma$. In atrial cardiomyocytes, activation of the β_2-adrenergic receptor causes G_s-mediated stimulation of AC (Sect. 5.2). Kir3 channels (Sect. 5.5) in these cells are opened by the $G\beta\gamma$ heterodimer in response to the activation of G_i by M2-muscarinic receptors. If subunits dissociate when G proteins are activated, and signal transduction occurs by a mechanism involving random collisions, then the $G\beta\gamma$ heterodimer produced when G_s is activated by the β_2-adrenergic receptor should also open Kir3 channels. However, this does not happen indicating that the cell has a way of ensuring that there is specificity with regard to G protein–mediated signaling.

The foregoing considerations raise caveats regarding the concept that proteins involved in G protein–mediated signaling

can move freely throughout the plasma membrane. The question now becomes: How does the cell control what signaling proteins interact with each other? The idea that biochemical pathways can be isolated is a long-standing notion. Historically, the term ''compartmentation'' has been used to describe the containment of a pathway by a subcellular organelle or microdomains within an organelle. Another effective means of compartmentation can be provided by the assembly of complexes through specific protein–protein interactions that include some components while excluding others. Compartmentation of G protein pathways within organelles, microdomains or by assembly into protein complexes is undoubtedly important for G protein–mediated signaling.

6.2 Compartmentation

Membrane microdomains identified as being sites where signaling components are concentrated include detergent-insoluble glycosphingolipid/cholesterol-rich rafts (DIGs), and small cavelike plasma membrane invaginations called caveolae. DIGs and caveolae are functionally defined as lipid microdomains that are resistant to dissolution in detergent. Among the signaling components found in these detergent-resistant membranes (DRM) are 7TM receptors, heterotrimeric G proteins, G protein–regulated enzymes and their substrates, and receptor and nonreceptor tyrosine kinases. In some cases, disruption of DRM can block signal transduction indicating that the integrity of these microdomains can be important in signal transduction. However, whether DRM contribute to the fidelity of signaling by segregating one signal transduction pathway from another remains to be determined.

6.3 Signal Transduction Complexes

6.3.1 Scaffolding Proteins

Colocalization of signaling molecules can occur through protein–protein interactions that produce molecular complexes. One mechanism of forming such complexes is to assemble them on the backs of scaffolding proteins. A distinguishing feature of many scaffold proteins is the presence of characteristic domains, often several of them, that are capable of binding to other proteins. Among the scaffolding domains that are important in the assembly of G protein–mediated signaling pathways are PDZ domains, PH domains, Src homology 2 and 3 (SH2 and SH3) domains, and GGL domains (Sect. 4.3). A number of proteins serve as scaffolding proteins for components of G protein–mediated signaling pathways.

Caveolins are proteins that are found in caveolae. The three isoforms, caveolin-1, -2, and -3, are 20 to 24 kDa integral membrane proteins whose N and C termini project into the cytosol. Caveolins serve as scaffolds that have the ability to bind many signal transduction proteins including G proteins, certain isoforms of AC, GRK2, PKA, PKC, the EGF receptor, Src, and Ras. In addition to scaffolding signaling molecules, caveolins can affect the activity of many of these proteins, and the interaction between caveolins and some signaling molecules can be regulated. The binding of caveolin to G proteins is influenced by the guanine nucleotide that is bound to $G\alpha$, and peptide fragments of caveolin can inhibit the steady state GTPase activity and

GTP binding to purified heterotrimeric G proteins suggesting the possibility of a direct interaction between caveolin and G proteins. Caveolins inhibit the activity of kinases involved in G protein–mediated signaling. Caveolin binds to the GRK N terminus, and inhibits GRK-mediated phosphorylation of 7TM receptors. PKA is also inhibited by caveolin.

The cytoskeleton can serve as a scaffold for proteins involved in G protein–mediated signaling, and numerous studies have demonstrated that disrupting the cytoskeleton affects signaling by G proteins. Tubulin, the principal component of microtubules, constitutes a large percentage of the protein associated with synaptic plasma membranes. The first indication that cytoskeletal proteins interact with components of G protein–mediated signal transduction pathways came with the observation that G_s could be washed from synaptic plasma membranes after treating them with microtubule-disrupting agents. Heterotrimeric G proteins bind to tubulin, as do $G\alpha$ and the $G\beta\gamma$ heterodimer individually, and the binding persists when nonhydrolyzable GTP analogs are bound to $G\alpha$. It was also discovered that tubulin can serve as a source of guanine nucleotides for the activation of G proteins. Cytoskeletal proteins interact with, and in some cases appear to regulate the activity of $G\alpha_s$, $G\alpha_{i1}$, $G_{q/11}$, PLCβ, and GRK. G proteins in turn, can regulate GTP binding to tubulin, GTP hydrolysis by tubulin, and tubulin polymerization.

AKAPs (A kinase anchoring proteins) are a structurally and functionally diverse group of proteins that share the ability to bind PKA (Sect. 5.2). PKAs are a heterotetrameric proteins designated as type I or type II depending upon the kind of regulatory subunit, type RI or RII, respectively, that they contain. Most of the known AKAPs bind type II PKA though several AKAPs capable of binding type I PKA have also been identified. AKAPs serve to target PKA to specific subcellular compartments, and disruption of the AKAP/PKA complex inhibits the cAMP-mediated effects of the kinase. In addition to PKA, many AKAPs bind other proteins that are involved in G protein–mediated signaling, including 7TM receptors, GRK, PKC, phosphatases, and β-arrestin. AKAPs have also been shown to regulate the activity of signaling proteins, for example, suppressing the activities of both phosphatases and kinases, and to anchor signaling complexes to the cytoskeleton as well. The ability of AKAPs to bind many signaling proteins simultaneously makes them ideal candidates for organizing entire pathways. Given their diversity, they may be able to selectively assemble the components of a particular signaling pathway, thus segregating it from others, and in so doing contribute significantly to the specificity of signal transduction. The feasibility of this hypothesis is suggested by data showing that only AKAP79/150 is coprecipitated with the β_2-adrenergic receptor from a detergent extract of rat brain that contain several AKAPs, but AKAP79/150 is not precipitated with α_{2A}-adrenergic receptors, AT_1-angiotensin receptors, or vasoactive intestinal polypeptide receptors.

Recent studies using both genetic and proteomic approaches have shown that many of the components used by *Drosophila* for detecting light are part of a large protein complex. Phototransduction in *Drosophila* is initiated by the light-induced isomerization of retinal converting the photoreceptor rhodopsin to metarhodopsin. This conformational change in the photoreceptor leads to activation of G_q and subsequently PLCβ

(Sect. 5.4). Activated PLCβ eventually triggers the opening of transient receptor potential (TRP) and TRP-like (TRPL) channels, and consequently leads to depolarization of the photoresponsive cell in approximately 20 ms. A number of proteins including PLCβ, calmodulin and a calmodulin binding protein called neither-inactivation or afterpotential C (*NINAC*) play a role in deactivation, which occurs in less than 100 ms. PLCβ, PKC, TRP, TRPL, NINAC, calmodulin, and rhodopsin are assembled into a complex by binding to the scaffolding protein inactivation no afterpotential D (INAD). INAD contains five distinct PDZ domains. Calmodulin binds to a region between the first and second PDZ domain of INAD, and PLCβ, PKC, TRP, TRPL, and NINAC bind to one or more of INAD's PDZ domains. INAD is critical for the efficient activation and deactivation of phototransduction in *Drosophila* and the evidence is consistent with its doing so by virtue of its ability to bring the various relevant signaling molecules into proximity by scaffolding them in what has been referred to as a tranducisome, signalsome or signalplex. There is evidence that the proteins involved in the mammalian phototransduction pathway are also scaffolded. A more extensive discussion of the signaling complex in mammalian visual system is presented in Sect. 7.2.

Juxtaposition of signaling components is important for both efficiency (speed of response) and specificity in the activation of MAP kinase cascades. In yeast, the MAP kinase cascade responsible for triggering mating (Sect. 5.8) is one of several MAP kinase pathways that are segregated from each other by virtue of being scaffolded into macromolecular complexes. In mammals, several proteins (JNK-interacting protein 1, MEK partner 1, and MEKK1) have been identified as candidates for scaffolding proteins that organize MAP kinase cascades. β-arrestin, in addition to its role in 7TM receptor desensitization (Sect. 3.2), plays a pivotal role in 7TM receptor-mediated MAP kinase activation. β-Arrestins scaffolds JNK3 (c-Jun amino-terminal kinase 3, a MAP kinase family member), MKK4 (a MAPKK), and ASK1 (apoptosis signal-regulating kinase 1, a MAPKKK) as well as Src, Raf, and ERK (Sect. 5.8). Indeed, there may be large signaling complexes containing dozens of proteins that include the components of both MAP kinase cascades and G protein–coupled signal transduction systems.

6.3.2 Complexes Containing Receptors, G Proteins, and Effectors

Scaffolding proteins can contribute to the efficacy of signal transduction by colocalizing many of the signaling molecules needed for the propagation of a signal as well as those that are responsible for terminating the signaling once the message has been received. Protein–protein interactions between the individual components of the pathway contribute in a similar way to the efficacy and fidelity of signal transduction. Despite the prevailing hypothesis that 7TM receptors, their cognate heterotrimeric G proteins, and the effectors that they regulate undergo transient bimolecular interactions, the literature of the last 30 years is peppered with data indicating that these proteins associate to form stable complexes.

One concept that has been challenged in recent years is the notion that 7TM receptors are present in cell membranes as monomers. There is now convincing biochemical, pharmacological, and biophysical evidence that 7TM receptors exist as oligomers (probably dimers) *in vivo*. Both homodimeric and heterodimeric complexes of 7TM receptors have been

identified, and heterodimeric complexes between different classes of 7TM receptors are possible. Studies involving the γ-amino butyric acid B ($GABA_B$) receptor revealed one of the functional consequences of receptor dimerization. There are two subtypes of the $GABA_B$ receptor (gb1 and gb2). Cells that express only one subtype do not produce a functional $GABA_B$ receptor, and gb1 when expressed by itself is retained in the ER. In contrast, cells that express both gb1 and gb2 produce functional heterodimeric $GABA_B$ receptors that are correctly transported to the plasma membrane, indicating a role for heterodimerization in the trafficking of receptors. Homodimerization of 7TM receptors may also play a role in the transport of receptors out of the ER. Other consequences of dimerization are that a particular 7TM receptor may display a different pharmacology, or couple to a different G protein depending upon the subtype of its dimeric partner. Not all 7TM receptors form dimers with other 7TM receptors. Two 7TM receptors, the calcitonin receptor and the related calcitonin receptor-like receptor, form heterodimers with receptor activity modifying proteins (RAMPs) that affect their pharmacology.

The concept that subunit dissociation occurs when heterotrimeric G proteins are activated also deserves scrutiny. The hypothesis that G protein subunits dissociate when activated is based almost exclusively on the behavior of purified G proteins in solution of detergent where activation requires incubating them with nonhydrolyzable GTP analogs such as GTPγS and unnaturally high concentrations (10–120 mM) of a divalent cation, usually Mg^{2+}. The high concentrations of Mg^{2+} serve to promote the dissociation of tightly bound GDP from Gα so that a GTP analog can bind in its place. In this way, Mg^{2+} is used to perform the function of a 7TM receptor. In addition to activating the G protein, these conditions cause Gα to dissociate from G$\beta\gamma$. However, high concentrations of Mg^{2+} cause G protein subunit dissociation in the absence of guanine nucleotides as well as in the presence of GDP, which does not activate the G protein, indicating that G protein subunit dissociation is not necessarily a consequence of activation. Activation of G proteins in solution under more nearly physiological conditions does not cause subunit dissociation, and experiments have demonstrated that the physical dissociation of G protein subunits is not necessary in order for them to regulate the activity of effectors *in vivo*. An activated heterotrimer G_s, rather than its dissociated subunits, is responsible for stimulating AC in cell membranes, and G_i subunits remain associated when activated in intact cells. These data together with data indicating that most effectors, including some isoforms of AC, PDE, Kir3, PLCβ, and PI3K, are regulated by or are at least interacting with both Gα and G$\beta\gamma$ make it increasingly likely that subunit dissociation does not occur, as a rule, when G proteins are activated *in vivo*.

There are many examples in which 7TM receptors and G proteins copurify. It is also apparent that a G protein can regulate the activity of an effector while remaining physically associated with its receptor. Studies have demonstrated that 7TM receptors are associated with their cognate heterotrimeric G protein *in vivo*, both before and during signal transduction. There is also evidence that G proteins form a complex with their cognate effectors regardless of whether or not the G protein is activated. Kinetic data support the existence of complexes containing both G proteins and effector *in situ*. Given data

that 7TM receptors form complexes with G proteins and that G proteins form complexes with their effectors, it is not surprising that stable complexes of 7TM receptors and effectors have been detected. The persistent association of G proteins with 7TM receptors, the stable association of G proteins with effectors, evidence that G protein subunits remain associated when the transducer is activated, and data showing that 7TM receptors are part of a complex with their cognate effectors *in vivo* are all consistent with the existence of stable signaling complexes containing 7TM receptors, G proteins, and effectors. These complexes are likely to include scaffolding proteins (Sect. 6.3.1) as well as other proteins that regulate signal transduction. For example, even though RGS proteins (Sect. 4.3) were originally recognized as interacting with certain G proteins, they also have collateral interactions with both receptors and effectors. These interactions are thought to contribute to an increase in signaling efficacy, but may also increase the stability of signaling complexes containing 7TM receptors, heterotrimeric G proteins, and effectors.

With evidence of the existence of signaling complexes has come the question of where these complexes are assembled. In order to be transported from the ER where they are made, to the plasma membrane where they signal, $GABA_B$ receptors must be assembled into heterodimers. A heterodimeric complex of a RAMP and a 7TM receptor (see above) has been reported to occur in the ER, and the formation of homomeric 7TM receptor complexes apparently take place in the ER. Studies indicate that peptide motifs contained in 7TM receptors constitute ER retention signals, and export from the ER requires that these motifs be masked by their association with other proteins. Similar processes appear to be required for the transport of effectors from ER to the plasma membrane. For example, some Kir3 channel subunits combine to form tetramers that are inserted into the plasma membrane, while other combinations are retained in the ER. These observations point to the ER as being the site where at least some assembly takes place. The ER may also be the site of more extensive interactions leading to the formation of signaling complexes containing 7TM receptors, G proteins, and effectors. If the heterotrimeric G proteins are assembled at the same time that receptors and effectors are incorporated into a signaling complex, this may explain how G proteins with a specific combination of $G\alpha$, $G\beta$, and $G\gamma$ subtypes are produced. Although $G\alpha$ subunits, and effectors for that matter, do not discriminate with regard to the subtype composition of the $G\beta\gamma$ heterodimer they interact with, receptors apparently have certain requirements in this regard (Sect. 6.1). Consequently, the presence of a receptor at the time a signaling complex is assembled may be responsible for dictating the subtype composition of the heterotrimeric G proteins that is associated with the signaling complex.

Most 7TM receptor agonists are membrane impermeable so that a response to the agonist requires that the receptors binding site be exposed on the extracellular surface. However, signaling complexes can be found in subcellular compartments other than the plasma membrane. A notable example is the pathway for mammalian phototransduction. Rhodopsin, G_t, and PDE are all located on an organelle within the cell known as the rod outer segment (ROS) disc. Since light can penetrate cell membranes there is no need for rhodopsin to be

in the plasma membrane. Other G protein–mediated signaling pathways occupy intracellular locations. Heterotrimeric G proteins are associated with the cell's mitotic machinery, and are involved in cell division. AGS proteins (Sect. 4.2) appear to be responsible for regulating G protein activity during mitosis though the mechanisms have not been entirely elucidated. The nuclear membrane has been shown to harbor functional G protein–mediated signal transduction pathways that are regulated by 7TM receptors, but it is not clear how, or whether these pathways are regulated by receptor agonists *in vivo*. Signaling complexes may be taken in by endocytosis and transported within the cell after activation as a way of delivering the message to its proper subcellular destination. For example, in neurons activated signaling, complexes translocate within the cell from nerve terminal to nucleus, and these complexes include heterotrimeric G proteins.

7
Signal Transduction: Striking A Balance Between Different Organizational Paradigms

7.1
Insight

Determining the paradigm used by cells to organize G protein-mediated signaling pathways has been an important goal for half a century. Early investigations, highlighted by the seminal work of Alexander Levitzki and Martin Rodbell suggested that these pathways were assembled into complexes of signaling proteins. In contrast, other work indicated that signaling proteins interacted transiently, and these data were predominant in shaping concepts of how signal transduction occurs in the cell. With time, more and more signaling molecules have been discovered, and individual cells are now known to contain many different signaling pathways that employ homologous signaling components with the potential to interact at cross-purposes if signal transduction were to rely entirely on a mechanism involving random collisions between signaling molecules. One consequence has been renewed interest in the hypothesis that G protein-signaling pathways are organized by being assembled into protein complexes, and much of the recent data have supported this hypothesis. Though early evidence for the existence of signaling complexes now seems prophetic, a stable protein complex does not provide the signal amplification that can be attained through transient bimolecular interactions, and this kind of amplification may be necessary for the response to certain stimuli (e.g. light). Thus, the contention between two competing hypothesis persists, and the extent to which transient interactions versus stable protein complexes contribute to G protein-mediated signal transduction remains to be determined. Although G protein-mediated signaling pathways share many characteristics, they must also differ in significant, though perhaps subtle ways including the extent to which they utilize protein complexes and transient interactions to achieve both efficacy and specificity during signaling.

7.2
Mammalian Phototransduction: A Tale of Two Signal Transduction Mechanisms

Within the mammalian retina are found two types of photoreceptor cells called rods and cones. Rod cells serve as sensitive detectors of light when ambient light

levels are low. Cone cells are less sensitive to light, and can be divided into three subtypes on the basis of the 7TM receptors they contain. The receptors in the different cone cells are distinct from one another in that they are activated by different wavelengths of light providing a basis for discerning colors. Rod cells have a structure that is referred to as the rod outer segment (ROS). ROS are easily isolated, and are highly enriched in the components required for phototransduction. These properties helped to make ROS the quintessential experimental system for studying G protein–mediated signal transduction. ROS discs are stacked one on top of another within the ROS, and encapsulated by the plasma membrane of the ROS. By the early 1980s, many of the proteins involved in this signaling pathway had been discovered, and the basic biochemical mechanism of phototransduction was understood. Rhodopsin, G_t, and PDE are bound to the ROS disc membrane so that they are all exposed to the cytoplasm. The ROS plasma membrane contains cyclic GMP-gated cation channels. In the dark, cyclic GMP (cGMP) produced by guanylyl cyclase binds to these channels and opens them allowing an influx of Na^+ ions. In its unactivated state, bovine rhodopsin has 11-cis retinal bound by a Schiff base linkage to lysine residue 296 in the receptor. When a photon causes the isomerization of retinal to the trans-configuration, it triggers a conformational change in rhodopsin (Sect. 3.1) that enables it to activate G_t. G_t subsequently triggers the activation of PDE, which reduces cGMP concentrations below those needed to keep the channels open. This stops the influx of Na^+ (and Ca^{2+}) ions causing the rod cell to become hyperpolarized. When darkness returns, G protein–mediated signaling is terminated so that PDE can no longer be activated by G_t, and the levels of cGMP increase causing the channels to reopen so that the rod cell is depolarized. Several mechanisms have been identified that attenuate the response to light. Some of these are necessary in order for the rod cell to adapt to a wide range of light intensities, while others are important for temporal aspects of the response to light. These mechanisms are not unique to phototransduction, and several have already been described. For example, an RGS protein (RGS9) acts as a GAP for G_t (Sect. 4.3), and activated rhodopsin is susceptible to desensitization by GRK1 and arrestin-1 (Sect. 3.2). Phototransduction is also a representative G protein–mediated signal transduction pathway in that it exhibits the characteristics of two organizational paradigms that appear to be mutually exclusive. On one hand, data supports phototransduction as occurring by a sequence of transient bimolecular interactions, while on the other, there is evidence that the components involved in phototransduction are organized into a signaling complex held together by a web of protein–protein interactions.

The original hypothesis that phototransduction is the consequence of a series of transient bimolecular interactions, first between rhodopsin and G_t and subsequently between G_t and PDE, is based on several observations. Together, rhodopsin, G_t, and PDE in a mole ratio of approximately 100 : 10 : 1 constitute about 90% of the protein present in ROS discs, and may be the only G protein–mediated signal transduction pathway in disc membranes. Thus, there is no need for a mechanism to isolate the phototransduction pathway from other G protein–mediated pathways in order to ensure the fidelity of phototransduction. When ROS discs are exposed to GTP in a low ionic strength buffer, G_t will dissociate from the membranes yielding an almost

pure preparation of the protein. This suggests that the G protein interacts weakly or transiently with the other components involved in phototransduction. Perhaps the most convincing evidence that signaling proteins interact transiently is provided by data showing that a single light-activated rhodopsin molecule can activate G_t at the rate of 10 to 200 s^{-1}.

In contrast, there are data suggesting that the interactions among rhodopsin, G_t, and PDE are not transient. Consider the following: Generally, 7TM receptors interact with heterotrimeric G proteins but only weakly with Gα or G$\beta\gamma$ individually (Sect. 6.1). This is true for the interaction of rhodopsin with G_t. Both Gα_t and G$\beta\gamma$ together, but not individually, will bind to liposomes or ROS membranes that contain rhodopsin. This is true regardless of whether or not the rhodopsin is light activated. When the nonhydrolyzable GTP analog, Gpp[NH]p, is bound to Gα_t, it becomes irreversibly activated, yet light-activated rhodopsin can cause the displacement of Gpp[NH]p from Gα_t suggesting that Gα_t-Gpp[NH]p can associate with G$\beta\gamma$ forming a heterotrimer that can also interact with activated rhodopsin. Furthermore, when the nonhydrolyzable GTP analog, GTPγS, is bound to Gα_t it can be cross-linked to G$\beta\gamma$ after incorporation into liposomes in the same way as the subunits of the unactivated holo G_t, thus providing additional support for the hypothesis that G_t can exist as an activated heterotrimer in lipid bilayers.

There are data indicating that the interaction of G_t with the effector PDE is not a simple transient interaction. PDE in ROS is a heterotetrameric ($\alpha\beta\gamma_2$) protein consisting of an 88-kDa α, and an 84-kDa β-subunit, each of whose catalytic activities are inhibited by the 13-kDa γ-subunits. Activated G_t binds to PDEγ preventing it from inhibiting the catalytic activity of PDEα and PDEβ. Activated G_t interacts directly with or can be cross-linked to all three of these PDE subunits, and evidence indicates that the Gα_t-GTP/PDEγ complex remains associated with PDEα and β on the membranes of ROS. Gα_t-Gpp[NH]p will activate PDE in solution, but its efficacy is greatly enhanced by liposomes or ROS membranes that contain light-activated rhodopsin. Covalent modifications that block Gα_t binding to rhodopsin, but do not affect its ability to activate PDE in solution, prevent rhodopsin from enhancing Gα_t-Gpp[NH]p-mediated activation of PDE. Since the affinity of Gα_t-Gpp[NH]p for rhodopsin by itself is low, the ability of rhodopsin to enhance the Gα_t-Gpp[NH]p-mediated activation of PDE is likely to be the result of a simultaneous cooperative interaction between rhodopsin, Gα_t-Gpp[NH]p and PDE. There is also evidence that unactivated G_t interacts with PDE suggesting that it may be in a complex with PDE in ROS membranes prior to the initiation of phototransduction. The majority of PDE, approximately 70%, is associated with ROS membranes while the remainder is soluble because the C termini of PDEα and PDEβ are associated with PDEδ subunits. Adding recombinant PDEδ causes PDE to be displaced from the ROS membranes with a concomitant loss in light-induced PDE activity, indicating that membrane localization of PDE is important for its activation by G_t.

The regulation of PDE activity is complicated by the fact that deactivation *in situ* occurs much more rapidly than the rate at which purified G_t hydrolyzes GTP. This prompted predictions that a GAP is involved in facilitating the catalytic activity of Gα_t (Sect. 4.3). Observations that PDE accelerates the rate of GTP hydrolysis by Gα_t led to the suggestion that PDE functions as

a GAP for G_t. Subsequently, it was discovered that a component separate from PDE is needed to accelerate the GTPase activity of $G\alpha_t$ in ROS membranes. The GAP activity of this component, now known to be RGS9, is facilitated by PDEγ, and the evidence suggests that it does so by increasing the affinity of $G\alpha_t$ for RGS9 in an allosteric fashion through binding to nonoverlapping sites on $G\alpha_t$. RGS9 is a tightly bound peripheral membrane protein of ROS, and the GGL domain of RGS9 binds to $G\beta_5$ (Sect. 4.3). RGS9 also binds to, and inactivates ROS guanylyl cyclase. Hence, there is evidence for a complex containing the PDE heterotetramer, $G\alpha_t$, RGS9, $G\beta_5$ and possibly guanylyl cyclase.

The interaction of RGS9 and $G\beta_5$ with PDE and $G\alpha_t$ are an example of collateral interactions that can contribute to complex formation. Other collateral interactions include those between G_t and the protein phosducin that serves to inhibit phototransduction. Phosducin binds holo G_t as well as $G\alpha_t$ and $G\beta\gamma$ individually. When the N-terminal and C-terminal domains of phosducin are produced separately, $G\beta\gamma$ will bind to the N-terminal domain of phosducin unless it is phosphorylated. In the absence of light, PKA mediates phosphorylation of phosducin on serine residue 73. Light-induced reduction of PKA activity leads to dephosphorylation of phosducin. It is proposed that the nonphosphorylated N-terminal portion of phosducin binds $G\beta\gamma$, thus inhibiting G_t-mediated signal transduction. This leads to an attenuation of the cell's response to light. In contrast, the phosphorylated form of phosducin predominates in the dark when PKA is activated, preventing phosducin from interfering with G_t function. The C-terminal portion of phosducin also binds to $G\beta\gamma$, and this site does not overlap with the site on $G\beta\gamma$ that binds the N-terminal regions of $G\alpha_t$, explaining how all three components can interact simultaneously to form a complex of phosducin with heterotrimeric G_t. Whether or not phosducin and G_t form a stable complex within membranes in the intact ROS remains to be determined.

Data support a role for scaffolding proteins in assembling many mammalian phototransduction proteins into a signaling complex. Two glutamic acid–rich proteins (GARPs) referred to as GARP1 and GARP2 as well as a glutamic acid–rich region of the cGMP-gated channel β-subunit referred to as the GARP' part have been identified as playing a role in scaffolding cGMP-gated cation channels, PDE, guanylyl cyclase, ATP-binding cassette transporter (aka. rim protein), and cytoskeletal proteins creating a signaling complex along the rim of the ROS disc where it is close to the plasma membrane. The interactions between PDE, G_t, phosducin, RGS9, $G\beta_5$ and rhodopsin could bring these molecules into a scaffolded complex as well. This signaling complex locates both the activating and attenuating pathways close to the ion channels that they regulate creating a configuration that may function both to prevent high rates of cGMP turnover during periods of intense illumination and to allow for rapid turn-on and turn-off of the response to light.

8 Clinical Importance

8.1 G Protein-mediated Signal Transduction in Diseases

Perturbations in the function of G proteins, their associated receptors and signaling systems have been linked to a number of human diseases including

asthma, heart disease, and cancer among others. Furthermore, recent studies have demonstrated that polymorphic variants (Sect. 9) of many of the proteins involved in G protein–mediated signaling can have consequences in the susceptibility, progression, and prognosis of these diseases. It has also been demonstrated that certain genetic mutations in genes coding for these proteins can result in agonist-independent constitutive signaling, which results in diseases such as precocious puberty, retinitis pigmentosum, and thyroid adenomas.

8.2 Heptahelical Receptors as Drug Targets

G protein–coupled signal transduction systems constitute the largest class of drug targets for the therapeutic treatment of diseases. More than 50% of all prescription drugs on the market today, including 20% of the top 50 selling drugs, directly or indirectly, target these systems, and account for over $20 billion of the pharmaceutical industry's annual sales worldwide. Furthermore, the potential for additional therapeutic drugs is considerable since currently available drugs target pathways that are controlled by only about 5% of the identified human 7TM receptors.

8.3 Potential for Therapeutic Treatments that Target G Protein–mediated Signaling Components Other than Heptahelical Receptors

The majority of drugs that target G protein–coupled signal transduction systems act as either 7TM receptor agonists or antagonists. By and large, attaining a specific therapeutic effect has depended upon the ability to produce ligands that bind selectively to a particular 7TM receptor. Some 7TM receptors have been shown to regulate the activity of more than one kind of effector by activating G proteins with distinct subunit composition. In such cases, targeting a specific pathway may be possible because of a phenomenon known as agonist trafficking. This term was coined to describe the observation that a particular ligand–receptor complex regulates the activity of different effectors with differing efficacies, and the rank order of efficacy for regulating the different effectors depends upon the specific receptor ligand. For example, agonists that bind to the serotonin2C receptor can regulate the activity of both PLC and indirectly phospholipase A_2, and the agonists 3-trifluoromethylphenyl-piperazine and lysergic acid diethylamide (LSD) preferentially activate PLC and phospholipase A_2, respectively. Agonist trafficking is thought to be a consequence of the receptor being able to exist in distinct conformational states that differ in their affinities for a particular ligand. The conformational state preferred by the receptor depends upon what proteins (*e.g.* G protein and effector) it interacts with. In this way, one signaling pathway may be specifically targeted by a particular agonist that would have little effect on other pathways coupled to the same receptor. This raises the possibility of developing pharmaceuticals with specificity for one pathway out of several that may be regulated by the same 7TM receptor.

Although the phenomenon of agonist trafficking offers the possibility of specifically targeting one of several pathways that are controlled by the same 7TM receptor, this goal may be difficult to attain in practice. An alternative approach is to target the interface between components that are unique to a given pathway (*e.g.* the interface between the receptor and the G protein) with peptidic and/or peptidomimetic

drugs. Such drugs may have greater therapeutic specificity, and fewer side effects than drugs that target the receptor binding site. Recent efforts have indeed seen a shift toward therapeutic targets other than the receptor binding site. Evidence supports the feasibility of using substances that either facilitate or inhibit protein–protein interactions as a way of modulating the activity of proteins, and recent studies indicate that G protein – signaling pathways will be amenable to these sorts of manipulations as well. Thus, a primary objective of future research will be to identify peptide motifs that are involved in protein–protein interactions. As the interfaces between the various signaling partners are identified, they will be scrutinized as potential targets for new drugs that can be used to modulate G protein – signaling pathways to therapeutic advantage.

9 Future Directions

If the DNA sequence of two individuals differs by a single nucleotide, and the frequency with which this occurs in a population is relatively high (1% or more), then this difference is called a single nucleotide polymorphism (SNP). It is estimated that a SNP occurs once in every 1000 bases, so the human genome contains several million SNPs. Some polymorphisms have severe consequences such as the SNP responsible for the Glu6Val substitution in hemoglobin that causes sickle-cell anemia, while others are silent causing no change in the gene product. SNPs that occur outside of the coding sequence for a protein may influence gene expression. For many diseases with a genetic component, polymorphisms are likely to be involved in their etiology, and with a few exceptions (*e.g.* sickle-cell anemia), multiple SNPs associated with different genes are liable to contribute. Variation in the response to drugs may also reflect differences in the spectrum of SNPs carried by one individual as compared with another. This interplay of genetics and pharmacology, referred to as pharmacogenomics, has made it important to identify SNPs, and to determine what SNP or combination of SNPs are associated with specific diseases or drug response. The prominence of 7TM receptors as drug targets makes them attractive subjects for probing the pharmacogenomic relevance of SNPs, and numerous SNPs have been identified in 7TM receptors. Many of these SNPs impact the properties of the receptors, and the same is likely to be true for SNPs in other signaling proteins. Knowledge of what genetic variants predispose an individual to disease will provide targets for gene replacement therapies once they become practical. In addition, understanding the correlation between drug response and genetic variation may make it possible to tailor therapeutic treatments to individuals so that maximum benefit can be achieved while avoiding undesirable side effects.

Keywords

Cytokines
A large family of secreted peptide ligands that bind to specific receptors on target cells to mediate potent biological responses. This includes immunomodulatory peptides from a number of important families including the TGF-β, TNF, and hematopoietin families.

GAS (Gamma Activation Site)
The enhancer element recognized by most activated STAT homodimers. It was first identified as an IFN-γ response element.

Hematopoietins
These four-helix-bundle cytokines mediate potent biological responses on target cells (see Table 1). They are predominantly involved in regulating inflammation and immunity.

IFN (Interferon)
A family of cytokines initially identified for their antiviral activity. This family includes the type I, type II, and λ IFNs.

IRFs (Interferon Response Factors)
A family of transcription factors that is important in immune response. They bind to the family of IFN response elements (IREs).

ISGF-3
An IFN-α-activated transcription factor consisting of Stat1, Stat2, and IRF-9.

ISRE (IFN-stimulated Response Element)
A specific enhancer that is recognized by ISGF-3. They constitute a subset of the IRE enhancer family.

JAK (Janus kinase)
Tyrosine kinase that associates with cytokine receptors and provides catalytic activity, which is essential to initiate signal transduction. Members include Jak1, Jak2, Jak3, and Tyk2.

Ligand
The specific peptide that binds to a receptor.

NK Cells (Natural Killer Cells)
A family of lymphocytes that are important in innate immunity. They are potently activated by IFN-I and secrete IFN-γ.

Protein Tyrosine Kinases
Enzymes that catalyze phosphorylation of protein tyrosine residues, which serve an important regulatory role in higher eukaryotes.

Receptors
Transmembrane-spanning proteins that specifically bind extracellular ligands, like hematopoietins, to mediate a biological response.

SH2 (Src Homology 2)
The domain that mediates protein–protein interactions through its capacity to recognize and bind to phosphotyrosines in the context of a specific sequence of amino acids, referred to as a *tyrosine motif* (see final entry). SH2-phosphotyrosine interactions play an important role in signal transduction.

SOCS (Suppressors of Cytokine Signaling)
A family of rapidly induced proteins that feed back inhibit JAK-STAT signaling.

STAT (Signal Transducers and Activators of Transcription)
A family of latent cytoplasmic transcription factors that transduces signals for cytokines. Members include Stat1, Stat2, Stat3, Stat4, Stat5a, Stat5b, and Stat6.

T cells
Thymic derived lymphocyte family whose members are activated by specific antigen-MHC complex. They constitute an important limb of adaptive immunity. They can be divided into several subsets including Th1 and Th2 cells.

Tyrosine Motif
A phosphotyrosine and the four-carboxy-terminal flanking amino acids that constitute an SH2 domain recognition/binding site.

Characterization of the ''viral interfering activity'' secreted by infected tissues led to the identification of interferons, the founding members of the cytokine family. Subsequent studies, directed at understanding how IFNs mediated their biological response then led to identification of the JAK-STAT signaling cascade. Today, the important role this pathway plays in transducing signals for the over 50 members of the hematopoietin family of cytokines is widely appreciated. After providing a brief historical perspective, this review will provide an overview of the JAK-STAT signaling cascade, with emphasis on some of the more recent developments in this field.

1 Introduction

In 1957, Isaacs and Lindenmann first described the potent antiviral properties of interferons (IFNs). It was not until 20 years later, when the IFNs had been purified to homogeneity, that the size and diversity of this family was recognized. They were segregated into two distinct families, now referred to as type I (i.e. IFN-α/β) and type II (i.e. IFN-γ) IFNs. The early generation IFN cDNA clones, circa 1980, served to propel them as one of the first products of a nascent biotechnology industry. Concomitantly, other secreted peptides, also with potent biological activity, were identified. These were initially referred to as *monokines* or *lymphokines*, reflecting their cellular source (i.e. monocytes and lymphocytes respectively). This confusing terminology was later replaced by more generic terms, interleukins (i.e. between leukocytes) and cytokines. The cytokine family of biological response modifiers has subsequently grown to number in the hundreds, including members of the four-helix bundle, TNF, TGF-β, growth factor, and chemokines families of ligands.

The early availability of relatively large quantities of purified recombinant IFNs provided an opportunity to determine

how these cytokines mediate their potent biological responses. Initial studies determined that the rapid induction of genes were an important feature of this response. Subsequent characterization of the ability of IFN-α to drive the expression of new genes led to the identification of Stat1, Stat2, and the JAK-STAT signaling cascade (STAT refers to signal transducers and activators of transcription and JAK refers to Janus kinase). Further studies determined that IFN-γ also signals through an analogous, but distinct JAK-STAT pathway.

Within three years, five additional members of the STAT family had been cloned and found to transduce signals for other members of the cytokine family of ligands. Subsequent gene targeting studies have confirmed the pivotal role the STATs play in transducing the biological response for each four-helix-bundle cytokines (see Table 1). More recent efforts have focused on understanding how the transient nature of STAT signaling is regulated. These studies have revealed an elaborate system of controls, including tight regulation

Tab. 1 Hematopoietin dependent JAK-STAT signaling. Hematopoietins transduce their signals through specific sets of JAKs and STATs as indicated. The assignments for which there is the most confidence (i.e. based on knockout and biochemical studies) are shown in bold. Those with less confidence are shown in plain lettering, and those with the least confidence are shown in brackets.

of nuclear import–export, phosphorylation, as well as novel regulatory proteins, most notably the SOCS (suppressors of cytokine signaling) family. As there are many excellent reviews on cytokines (i.e. hematopoietins) and JAK-STAT signaling, this review will focus on the more recent developments and the important role IFN studies have played in elucidating hematopoietin biology.

2 Discovery of the JAK-STAT Signaling Paradigm

Studies with early preparations of recombinant IFN-Is led to the identification of a set of rapidly induced genes. Classic promoter analysis of these IFN-stimulated genes (ISGs), identified a single conserved IFN-stimulated response element (ISRE), with a consensus of $AGTTTN_3TTTCC$. Three unique ISRE binding complexes were identified in nuclear extracts prepared from IFN-α–stimulated cells. They were named *IFN-stimulated gene factor 1* (ISGF-1; aka IRF-2), ISGF-2 (aka IRF-1), and ISGF-3. Kinetic and biochemical studies suggested that ISGF-3 was the critical factor directing the rapid expression of IFN-α stimulated genes. Purification of ISGF-3 led to the identification of four component proteins, with molecular weights of 113 kDa, 91 kDa, 84 kDa, and 48 kDa. The 48-kDa protein was recognized as the ISRE binding component of this complex. Analysis of the three larger proteins determined that they were members of a novel family of proteins, for which the term STAT was coined. The 84 and 91 kDa proteins turned out to

be alternative mRNA splice products of a single gene and were renamed Stat1α and Stat1β. The 113-kDa product became known as Stat2 and the 48-kDa protein, with its homology to interferon response factors (IRFs) was named IRF-9.

With the development of antibodies against Stat1 and Stat2, it was possible to demonstrate that both proteins resided in the cytoplasm of resting cells. Upon IFN-α stimulation, Stat1 and Stat2 (both isoforms) were rapidly phosphorylated on a single conserved tyrosine, leading to the formation of stable Stat1–Stat2 heterodimer. Subsequent biochemical and structural studies determined that STAT dimerization is driven by the stable interaction between the phosphotyrosine residue of one STAT with the SH2 (Src homology 2) domain of the corresponding STAT. In contrast to the inactive STATs, Stat1–Stat2 dimers are competent for translocation into the nucleus, where they associate with IRF-9 to form a stable ISRE DNA binding complex, and direct the expression of target genes (see Fig. 1). Numerous ISRE-driven genes have been characterized, including PKR (the dsRNA dependent protein kinase), OAS (2′-5′ oligoadenylate synthetase), Mx, PML, the

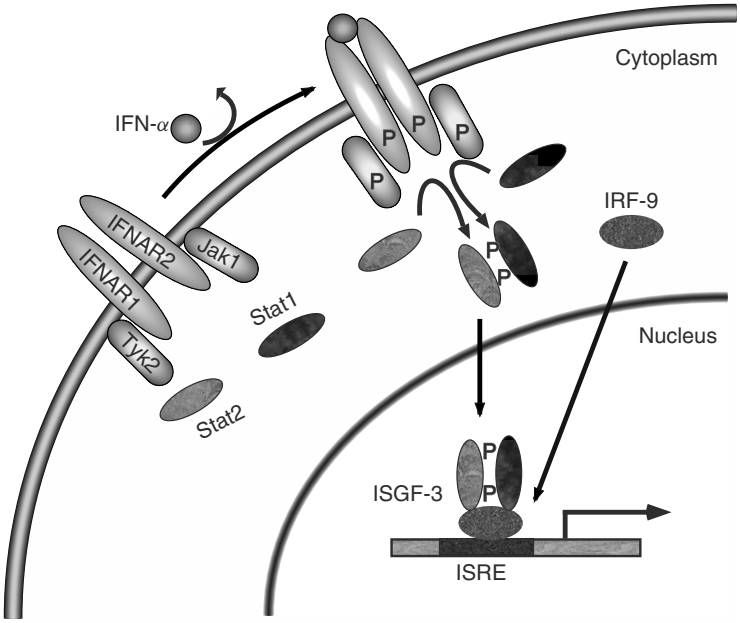

Fig. 1 The IFN-I signaling paradigm. Upon binding to its dimeric receptor, type I IFN promotes the apposition of two receptor associated JAKs, which then activate each other by transphosphorylation. The activated JAKs in turn phosphorylate receptor tyrosine(s), directing the SH2 domain dependent recruitment of Stat1 and Stat2. At the receptor, Stat1 and Stat2 are activated by phosphorylation, whereupon they heterodimerize, translocate into the nucleus, and associate with IRF-9 to bind to the ISRE enhancers. This DNA binding complex, referred to as ISGF-3, directs the expression of ISRE target genes. IFN-I also promotes the formation of Stat1 homodimers, which directs the expression of GAS-driven genes as outlined in Fig. 2.

Ifi 200 cluster, GBP, iNOS (inducible nitric oxide synthetase, aka NOS2), IP-10, IRF-7, 9–27, and ISG-15.

Contemporaneous with the discovery of STATs, was the recognition that members of the JAK family of tyrosine kinases were important in IFN-I signaling. This provided the missing link as to how STATs were activated and the term JAK-STAT Pathway was coined. Parallel efforts to understand how IFN-γ mediated potent but distinct biological responses led to the discovery of an analogous yet different JAK-STAT signaling pathway (see Fig. 2). Notable similarities with the IFN-α signaling cascade included requirement of a unique receptor, JAKs and Stat1. As was the case with IFN-α, elucidation of this pathway began with the identification of an IFN-γ responsive element (i.e. the gamma activation site; GAS) in the promoters of GBP and FcγRI. Subsequently, a unique IFN-γ-induced GAS binding activity was recognized and determined to consist of Stat1. Moreover, IFN-γ was found to stimulate the phosphorylation of the same conserved tyrosine residue on Stat1 as IFN-α. However, in the absence of Stat2 activation, a Stat1 homodimer was formed that translocated into the nucleus and directly bound DNA, culminating in the expression of GAS-driven genes. Subsequent studies determined that all STATs, with the exception of Stat2, form homodimers upon activation and then directly bind members of the GAS family of enhancers. This family of conserved enhancers features a palindrome, where the

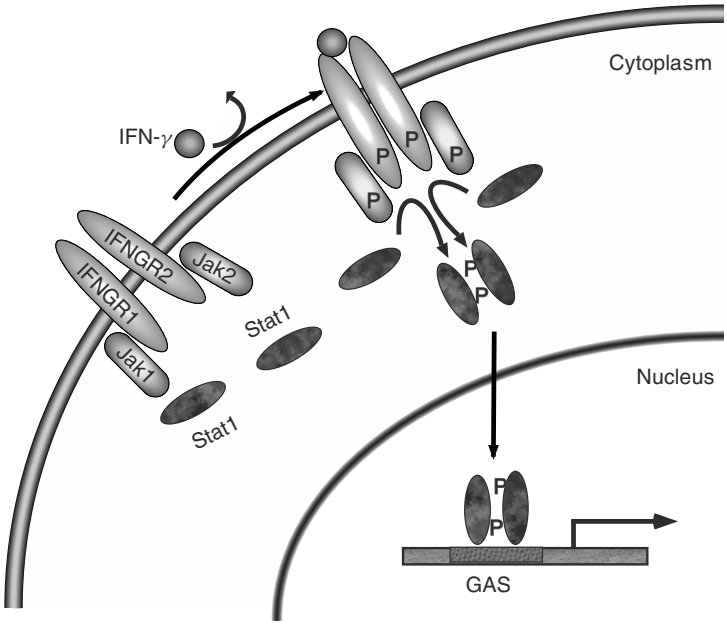

Fig. 2 The IFN-II signaling paradigm. Upon binding to its dimeric receptor, IFN-γ promotes the activation of two receptor associated JAKs. The activated JAKs in turn activate the receptor. Stat1 is recruited to the receptor, whereupon it is activated and forms homodimers. Stat1 homodimers translocate to the nucleus and bind to the GAS family of enhancers, culminating in the expression of a distinct set of genes.

optimal sequence is $TTCN_{2-4}GAA$ (Stat1 homodimers bind to an element where $N = 3$; Stat3 homodimers favor $N = 2$; and Stat6 homodimers favor $N = 4$). IFN-γ stimulated GAS-driven genes include a number of important immunoregulatory transcription factors (e.g. IRF-1, ICSBP and CIITA), chemokines (e.g. Mig), and cell surface molecules (e.g. ICAM-1, Ly6E and FcγRI). CIITA is critical for adaptive immunity, driving the expression of major histocompatibility complex (MHC) class II and the Invariant chain, whereas IRF-1 has more broad effects, directing the expression of immune response genes like *iNOS, MHC I, LMP2, TAP2,* and *IL-12*. The ability of IRF-1 also to drive ISRE gene expression is likely to account for some of the overlap in the biological responses to IFN-α and IFN-γ.

The rapid identification of additional members of the STAT family provided an opportunity to determine that the other four-helix-bundle cytokines (i.e. hematopoietins) also transduce signals through this pathway. As the number of four-helix-bundle cytokines has grown, so has the recognition that they all transduce pivotal signals through JAK-STAT signaling cascade. The critical role hematopoietins play in directing immune response has directed further attention to this important pathway.

3 The Janus Kinases (JAK) Family

Studies directed at understanding how IFNs mediated biological response directly implicated three known members of the JAK family, Jak1, Jak2, and Tyk2 in signal transduction. Subsequent homology screens identified a fourth member, Jak3, whose expression was restricted to hematopoietic tissues. However, each of these JAKs shared important structural and functional features that enable them to serve as an essential kinase for cytokine receptors. This is also the case for a JAK homolog, Hop, which has been identified in *Drosophila melanogaster* (see Sect. 4.1).

3.1 JAK Structure

JAKs range in size from 120 to 130 kDa. Comparison of these ~1000 residue kinases reveals seven high homology regions, JH1–JH7 (see Fig. 3a). JH1 encodes the tyrosine kinase, whose activity is regulated by an activation loop. Thus, in resting cells when the activation loop sits in the catalytic pocket, activity is limited to a low or basal state. However, cytokine dependent ligation brings the two receptor associated JAKs into close apposition, enabling them to activate each other through a transphosphorylation event. This entails exploiting basal activity to phosphorylate the opposing kinases activation loop. The loops move out of the catalytic site, rendering these kinases fully active, whereupon they sequentially phosphorylate critical receptor and STAT tyrosine residues (see Figs. 1 and 2). The second JAK homology domain, JH2, represents a pseudokinase domain (i.e. catalytically inactive) that is both a signature feature of this kinase family and appears to be required for full catalytic activity. The five amino-terminal JAK homology domains, JH3–JH7, constitute a FERM (four point one, ezrin, radixin, moesin) domain, which is responsible for association with hematopoietin family of cytokine receptors. Specifically, JAKs associate with proline rich, membrane proximal box1/box2 domain found in these receptors. As outlined in Sect. 5,

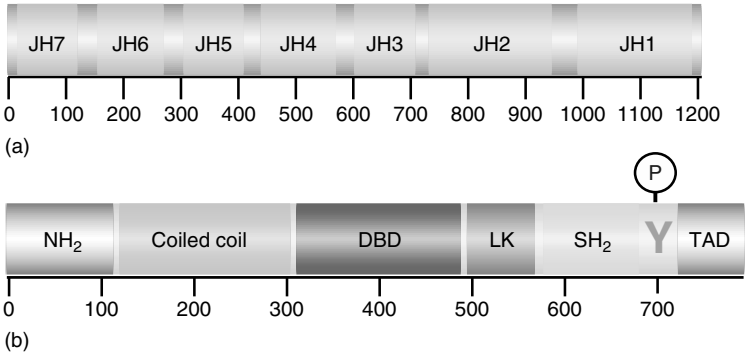

Fig. 3 Structural models of the JAK and STAT family of signaling proteins. (a) The four members of the JAK family share seven homology domains regions, JH1–JH7. JH1 serves as the catalytic domain, whereas JH2 represents a pseudokinase domain, which is a characteristic feature of this family of tyrosine kinases. JH3–JH7 comprise a FERM domain that is responsible for association with cytokine receptors. (b) The seven members of the STAT family of transcription factors share seven functionally conserved domains. This includes the amino-terminal domain (NH_2), the coiled-coiled domain (coiled coil), the DNA binding domain (DBD), the Linker domain (LK), the SH2 domain, the tyrosine activation domain, and the transcriptional activation domain (TAD), which is conserved in function but not in sequence. Domain colors correspond with those in Stat1 Crystal structure in Fig. 4.

the cytokine receptors depend on JAKs to transduce signals that can be functionally divided into several groups, each exhibiting a unique pattern of JAK association and STAT activation (see Table 1).

3.2 JAK Family Members

3.2.1 Jak1

This kinase was initially recognized for its association with the second chain of the IFN-α receptor (IFNAR2) and then the first chain of the IFN-γ receptor (IFNGR1). Subsequent biochemical studies demonstrated association with receptors for the gp130 and the common γ (γC) families. Jak1 knockout mice die perinatally, secondary to neurological defects attributed to a loss in gp130 signaling. Jak1$^{-/-}$ mice also exhibit reduced lymphocyte counts due to a lack of T cells and NK (natural killer) cells. Biochemical studies on Jak1$^{-/-}$ cells have underscored a failure to respond to cytokines from the gp130, γC, and IL-10 families.

3.2.2 Jak2

This kinase was initially determined to associate with IFNGR2 and the gp130 component of the IL-6 receptor. Targeted deletion of Jak2 yielded embryonic lethal phenotype, at day 12.5, due to failure in definitive erythropoiesis. Tissues collected from Jak2 knockout mice fail to respond to IFN-γ and most of the cytokines from the IL-3 and single-chain cytokine receptor families (see Table 1).

3.2.3 Jak3

The expression in this JAK is limited to hematopoietic cells, where it exclusively associates with the γC chain. Hence, the Jak3 knockout mice exhibit a severe combined immunodeficiency disease (SCID)

like syndrome, analogous to what has been reported for γC deficient mice.

3.2.4 Tyk2

Although the first member of the family to be associated with cytokine signaling, it was the last to be knocked. Earlier biochemical studies implicated Tyk2 in IFN-I, IL-10, IL-12, and IL-13 signaling. Yet, Tyk2 knockout mice exhibit surprisingly modest defects in their response to IFN-I and IL-10. They do, however, exhibit significant defects in their response to IL-12, and unexpectedly profound defects in their responses to LPS. While the mechanism behind this latter defect is not fully elucidated, it underscores the intimate relationship between toll-like receptor (TLR) dependent signaling (LPS signals through TLR-4), IFN-I production, and the IFN-I autocrine loop (see also Fig. 5).

4 The STAT Family of Transcription Factors

The rapid identification of seven members of the STAT family facilitated a functional classification of the growing family of cytokine receptors (see the following and Table 1). It also provided an opportunity to explore STAT function. The seven mammalian STATs (Stats 1–6 with two Stat5 genes), range in size from 750 to 900 amino acids. They consist of six distinct domains (Fig. 3b), and except for Stat2, they all transduce signals through the paradigm illustrated in Fig. 2. STATs have also been identified in numerous more primitive model eukaryotes, including *D. melanogaster*, *Caenorhabditis elegans*, and *Dictyostelium*. Growth in the number of STATs during evolution that appears in these lower eukaryotes reflect an increasing need for cell-to-cell communication as eukaryotes have become more complex.

4.1 STAT Evolution

STATs have been remarkably well conserved during eukaryotic evolution and may encode the primordial SH2 domain (see Sect. 4.2.5). Homologs have been identified in *Dictyostelium, C. elegans, Drosophila, Anopheles, Xenopus*, and zebrafish. The JAK-STAT pathway has been genetically characterized in *Drosophila*, where it plays important roles in developmental segmentation, larval hematopoiesis, sexual identity, and the development of eye polarity. The single *Drosophila* JAK exhibits 27% identity to Jak2 and the single STAT exhibits 37% identity to Stat5. Also present in *Drosophila* are a distant homolog of a cytokine receptor (Upd) and ligand (Dom). The three STAT homologs in *Dictyostelium* are distantly related to mammalian Stat5 and Stat3, but the signaling pathways they are involved in are unrelated to the one found in *Drosophila* and vertebrates. STAT homologs in *C. elegans* are also more distantly related. Zebrafish encode two STATs, homologous to Stat1 and Stat3. The Stat3 homolog is expressed in early development and is syntenic with both murine and human Stat3. The zebrafish Stat1 homolog is more divergent and expressed later in life.

The seven murine and human STATs are segregated into three syntenic genetic clusters, each consisting of two tandem STATs and suggesting evolution from a single tandem cluster (see the following). Specifically, in mice, Stat1 and Stat4 map to chromosome 2; Stat2 and Stat6 map to chromosome 12; and Stat3 and Stat5 map to chromosome 17. The Stat5 gene,

however, has undergone an additional evolutionarily more recent duplication, yielding tandem Stat5a and Stat5b genes. Analysis of these clusters, the recent duplication of Stat5, and the sequence conservation of Stat3 and Stat5 amongst lower eukaryotes, all serve to suggest that Stat3–Stat5 gene cluster represents the primordial tandem array mammalian STAT genes. This may also explain the relative functional pleiotropy of these two STATs (see the following).

4.2 STAT Structure

Biochemical, genetic, and structural studies have provided clear evidence that each of the seven mammalian STATs consist of six domains, as well as a tyrosine near residue 700 that serves as the activation site (see Figs. 3b and 4). These functionally conserved domains include: the amino-terminal domain (NH_2), the coiled-coiled domain (CCD), the DNA binding domain (DBD), the linker domain, the SH2 domain and the carboxy-terminal transcriptional activation domain (TAD; conserved in function but not sequence).

4.2.1 NH_2 Domain

The amino-terminal domain, about 130 residues in length, forms a unique dimeric structure when crystallized as an independent domain. Likewise, biochemical and genetic studies of full-length inactive Stat1, Stat3, Stat4, and Stat5 indicate that the amino-terminal domain drives homotypic

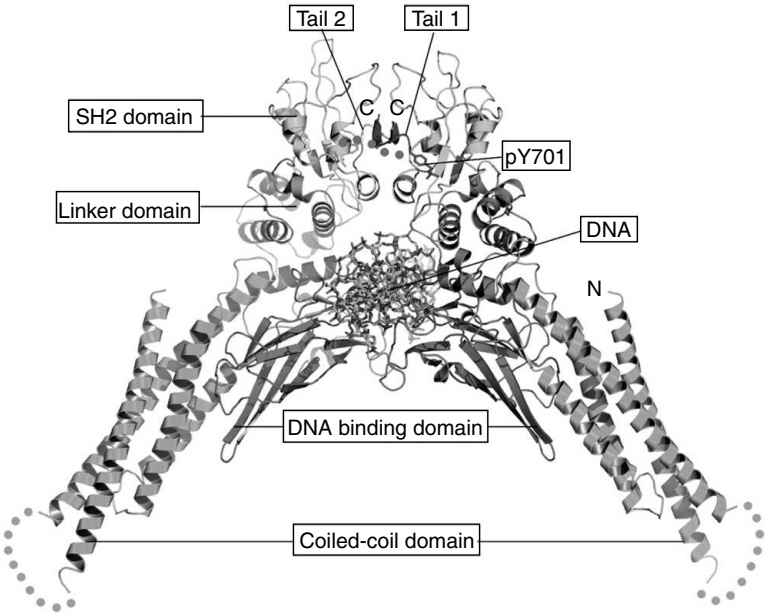

Fig. 4 Stat1 crystal structure. The structure represents two activated Stat1 fragments (amino acids 135–710) that are dimerized and bound to a GAS palindrome. Each domain is shown in a distinct color and labeled (see Fig. 3). Note that the CCD forms a four-α-helix bundle and the DBD forms a β-barrel with an immunoglobulin fold (see color plate p. xlii).

(i.e. to self) dimerization. This may assure delivery of ''packets'' of STAT dimers to the receptor in a conformation that renders the tyrosine, near residue 700, exposed. Upon activation, STATs undergo a conformation change, in which this phosphotyrosine becomes buried in an activated structure. Earlier studies also implicated the ability of the amino termini to dimerize, thereby promoting cooperativity of DNA binding to tandem GAS elements. Finally, the amino terminus may also serve to regulate STAT nuclear import and export.

4.2.2 Coiled-coil Domain

This amino proximal domain, ~150 residues in length (amino acids 135 to 315 for Stat1), folds up into a four-α-helix bundle (see Fig. 4). This structural feature is likely to afford the ability to dynamically regulate interactions with regulatory proteins (e.g. karyophilins) and a large surface area for protein–protein interactions. Consistent with this, the coiled-coil domain protrudes 80 Å laterally from the core structure of both Stat1 and Stat3, providing a hydrophilic surface that is known to associate with other proteins including IRF9, c-Jun, N-myc interacting protein (Nmi), and StIP.

4.2.3 DNA Binding Domain

This highly conserved ~200 amino acid domain (residues 320–480 in Stat1) forms a β-barrel with an immunoglobulin fold, reminiscent of the NF-κB and p53 DBDs. This affords each STAT component in the dimer the ability to recognize bases in the proximal half of the GAS palindrome. The number of direct contact sites between STAT residues and DNA are modest, yielding a dissociation constant in the nanomolar range, and suggesting that cooperative DNA binding activity may be an important aspect for STAT function. Recall, that Stat2 does not appear to form active homodimers or bind DNA directly.

4.2.4 Linker Domain

As the name suggests, this short domain (amino acids 488–576 for Stat1), links the DBD with the SH2 domain. Detailed analysis of the linker structure suggests that this domain serves to appropriately ''translate'' the SH2 dependent dimerization to the DBD.

4.2.5 SH2 and Tyrosine Activation Domain

The STAT SH2 domain is the most highly conserved and arguably the most important domain (residues 580–680 in Stat1). It plays critical roles in signal transduction through its capacity to recognize specific receptor phosphotyrosine motifs (i.e. affecting specific receptor recruitment). After activation it specifically recognizes the phosphotyrosine motif on the partner STAT (i.e. directing active STAT dimerization). Moreover, the SH2 domain in *Dictyostelium* STAT appears to represent the ''earliest'' identified SH2 domain, raising the possibility that it is the primordial SH2 domain. Although the STAT SH2 domain is well conserved evolutionarily, it is surprisingly divergent from other SH2 domains in sequence, but not structure. The structure consists of an antiparallel β-sheet, flanked by two α-helices, forming a pocket. An absolutely conserved arginine (Arg-602 for Stat1) resides at the bottom of this pocket and mediates the interaction with phosphotyrosine. As is the case with all SH2 domains, flanking residues recognize the other amino acids that are characteristic of a tyrosine motif (i.e. phosphotyrosine + four carboxy-terminal amino acids). Of note, the residues most important in defining

the specificity of binding to the STAT tyrosine motif (i.e. the tyrosine activation domain) during dimerization are located at positions +1 and +3 in this motif. In Stat1 residues, +5, +6, and +7 also contribute to the specificity of dimerization by associating with Ala-641 and Val-642 of the SH2 domain. The proximity of the SH2 to the corresponding STAT tyrosine activation domain precludes an intramolecular association between these domains. Thus, the STAT SH2 domain is only able to bind to tyrosine motifs on other proteins.

4.2.6 Transcription Activation Domain

The critical TAD resides at the STAT carboxy terminus. Consistent with the ability of this domain to regulate unique transcriptional responses for each STAT, it is the most poorly conserved STAT domain. The function of this domain can be regulated by either deletion or serine phosphorylation. The former feature was recognized with the initial isolation of Stat1β (i.e. the 84 kDa ISGF-3 component), which is an alternate splice isoform. The *Stat3* gene gives rise to a similar carboxy terminally deleted Stat3 isoform, Stat3β. Intriguingly, recent studies suggest that truncated isoforms are not necessarily transcriptionally inert, but rather can also direct the expression of a unique gene program through the association with distinct sets of transcriptional regulators. Regulation of STAT transcriptional activity by serine kinases has also received considerable attention. These studies have identified numerous candidate serine kinases, potentially reflecting the ability of multiple "stress" pathways to modulate STAT activity. Elegant studies, in which the critical serine residue in Stat1 and Stat3 have been mutated by a knockin approach, have demonstrated that serine phosphorylation is important for the expression of a subset of STAT target genes.

4.3 STAT Family Members

As indicated above, seven STAT genes have been identified in both mouse and man. They include *Stats1–6* and two Stat5 genes, *Stat5a* and *Stat5b*.

4.3.1 Stat1

Both biochemical and gene targeting studies have determined that Stat1 is critical for both type I and type II IFN signaling (see Figs. 1 and 2). Stat1 forms transcriptionally active homodimers in response to stimulation with both classes of IFNs (studies with λ-IFNs are under way; see Sect. 5.1.3). IFN-Is and IFN-λs also direct the formation of active Stat1–Stat2 heterodimers. Intriguingly, the relative role that Stat1 homodimers versus Stat1–Stat2 heterodimers play in the biological response to IFN-Is is tissue specific, with Stat1–Stat2 heterodimers playing a considerably more prominent role in fibroblasts and epithelial cells. Finally, gene targeting studies have also underscored a modest role for Stat1 in the biological response to IL-6 (see Table 1). Specifically, Stat1 appears to alter the nature of the response to Stat3 (the major gp130 activated STAT; see Sects. 4.3.3 and 5.2.2), highlighting the seemingly antagonistic roles Stat1 and Stat3 play in cancer and immune response. That is to say, numerous studies have implicated Stat3 as an oncogene, whereas Stat1 appears to antagonize cell proliferation. Likewise, Stat1 drives the expression of proinflammatory genes (aka "danger signals"), whereas Stat3 activation

can be associated with the suppression of inflammation.

4.3.2 Stat2

Stat2 is a most unique member of the STAT family by virtue of its large size, inability to homodimerize, and inability to directly bind DNA. Sequence comparison of the murine and human homologs also reveals an uncharacteristic level of carboxy-terminal sequence divergence. Both biochemical and gene targeting studies have determined that Stat2 is critical for the biological response to IFN-Is. Upon activation, Stat2 heterodimerizes with its exclusive partner Stat1. This heterodimer is competent for nuclear translocation, but must associate with IRF-9 to form a stable complex on ISRE elements, a signaling paradigm that is unique to Stat2 (see Fig. 1). Biochemical studies have suggested a similar role in the response to λ-IFNs. Although gene targeting studies have highlighted an essential role for Stat2 in IFN-I signaling, there is growing evidence for a regulatory role in some IFN-γ responses.

4.3.3 Stat3

Biochemical and gene targeting studies have demonstrated that Stat3 plays a critical role in mediating the biological response to members of the IL-6/gp130 and IL-10 families of cytokines. Underscoring an important developmental role for gp130 dependent signals, deletion of the *Stat3* gene yields an early embryonic lethal phenotype (i.e. day 6.5–7.5). However, tissue-specific deletions of Stat3 are largely associated with abnormal inflammation and/or decreased susceptibility to cancer. As suggested by the latter phenotype, there is a burgeoning interest in understanding the role Stat3 plays in tumorigenesis. This contrasts the biological activities associated with Stat1, pointing to the seemingly antagonistic relationship between Stat1 and Stat3 with respect to the control of growth and inflammation alluded to in Sect. 4.3.1.

4.3.4 Stat4

Stat4 is predominately involved in signaling for the IL-12 family (see Table 1 and Sect. 5.2.3), which plays a critical role in activating the effector functions of both Th1 and NK cells (e.g. enhanced IFN-γ production). Studies on Stat4 and Stat6 (see Sect. 4.3.6) knockout mice have underscored the important role these two STATs play in maintaining a healthy balance between Th1 and Th2 dependent immune responses. More recent studies have also implicated Stat4 in the ability of IFN-Is to synergize with IL-18 in the activation of Th1 cells. For these responses, IFN-I has been shown to drive Stat4 tyrosine phosphorylation and IL-18 to stimulate Stat4 serine phosphorylation, both of which are required for full activity. Although Stat4 is also important in the biological response to IL-23, a potential role in the biological response to the two newest members of the family, IL-27 and IL-30, remains more controversial.

4.3.5 Stat5a and Stat5b

Consistent with their location in the primordial STAT locus, Stat5a/Stat5b, like Stat3, are relatively pleiotropic in their effects. They transduce important signals for all members of the IL-2 family (all γC receptors except for IL-4 and IL-13), the IL-3 family, and the single-chain receptor family (see Table 1). Underscoring their homology, Stat5a and Stat5b play overlapping roles in mediating the responses to IL-2 and IL-3 ligand families.

Surprisingly however, the responses to members of the single-chain family are far more specific. Stat5a knockout mice exhibit a profound defect in the response to prolactin (PRL), and Stat5b knockout mice exhibit a profound defect in the response to growth hormone (GH). Reproductive defects and an autoimmune phenotype, attributed to a deficient IL-2 response, have made Stat5a/5b double knockout mice difficult to propagate and study.

4.3.6 Stat6

Biochemical and gene targeting studies have determined that Stat6 transduces signals for two closely related and distinct members of the γC family of receptors, the IL-4 and IL-13 receptors. Both receptors, and their corresponding ligands, play an essential role in the development of an effective Th2 dependent response. Thus, as outlined above, Stat4 and Stat6 serve as protagonists in maintaining a critical balance between the Th1 and Th2 subsets of T-helper cells.

5 Hematopoietin Family of Cytokine Receptors

To date, over 50 members of the four-helix-bundle family of cytokines, also referred to as *hematopoietins*, have been identified. They each bind to a conserved family of receptors, referred to as *hematopoietin receptors*, or more commonly known as *type I* and *type II cytokine receptors*, based on the presence or absence, respectively, of a conserved WSXWS amino acid sequence motif in their extracellular domain. Members of the cytokine receptor family type I can be further subdivided into four functionally related groups that transduce signals through analogous JAK-STAT signaling pathways (see Sects. 5.2–5.5; see also Table 1). Members of the cytokine receptor family type II (CRF2) include receptors for the many members of the IFN and IL-10 ligand families. Consistent with this, they also signal through a characteristic, albeit more pleiotropic set of JAK-STAT signaling pathways (see Sect. 5.1; see also Table 1).

5.1 The Cytokine Type II or IFN Receptor Family

IFNs represent the largest single family of cytokines that bind to and signal through receptors composed of CRF2 chains. Until recently, IFNs were divided into two families, type I and type II, on the basis of distinct receptors they bind. However, recently a third family of "λ-IFNs" has been identified, which signal through a unique receptor, consisting of an IL-10 receptor chain and an "orphan" CRF2 chain. The related IL-10 family of ligands also binds to a partially overlapping set of receptors consisting of CRF2 chains.

5.1.1 Type I IFN Receptor

Ligands binding to the type I IFN receptor represent the largest single family of four-helix-bundle cytokines, numbering close to 20 in man and mouse. Referred to as type I IFNs (IFN-Is), they are encoded in a large locus of single exon genes. IFN-Is include numerous IFN-αs, IFN-β, IFN-δ, IFN-ε, IFN-κ, IFN-τ, IFN-ω, and Limitin. Their receptor, which is usually referred to as the IFN-α receptor (IFNAR), is expressed in all cells. It consists of two CRF2 chains, IFNAR1 and IFNAR2. The cytoplasmic domain of IFNAR1 is physically associated with Tyk2,

whereas the cytoplasmic domain of IFNAR2 binds Jak1. As outlined in Fig. 1, upon binding IFN-I, these receptor associated tyrosine kinases become activated by transphosphorylation, whereupon they phosphorylated receptor tyrosine(s) to affect STAT recruitment (see Sect. 3.1). At the receptor, Stat1 and Stat2 become phosphorylated (i.e. activated) and form both Stat1–Stat2 heterodimers and Stat1 homodimers, which in turn direct the expression of ISRE- and GAS-driven genes. The relative balance of these two pathways differs between tissues, with Stat1–Stat2 dimers playing a more important role in fibroblasts and macrophages relying more heavily on Stat1 homodimers. Although IFN-Is were initially recognized for their important role in the innate immune response to viral infection, they are now also recognized for their capacity to regulate the interface between innate and adaptive immunity. Consistent with their important role in immune response, the regulation of IFN-I expression is quite complex (see Fig. 5). During infection with either a viral or bacterial pathogen, pattern recognition receptors, often from the TLR family, become activated. These receptors trigger activation of IKK-ε (aka IKK-i) and TBK-1, culminating in the activation of IRF-3. Activated IRF-3 drives the expression of IFN-β, the prototypical immediate early IFN-I. IFN-β is secreted, and binds to the IFN-α receptor directing the activation of ISGF-3 and expression of ISRE-driven genes. One such target gene, *IRF-7*, either independently or along with *IRF-3* (and potentially other IRFs) directs the robust secretions of the many delayed IFN-Is (e.g. IFN-αs, IFN-δ, IFN-ω, etc.). Intriguingly, the IFN-I autocrine/paracrine loop appears to be active at low levels in resting cells (i.e. basal activity), potentially underscoring its role as a sentry for infection. More recently however, studies have implicated this autocrine loop in the regulation of noninfectious cellular stresses, including cancer and autoimmune disease. Finally, while it is clear that both Stat1 and Stat2 play a critical role in mediating IFN-I response, the role other STATs play in this response has remained more controversial. Recent studies suggest that Stat3, which is activated by IFN-Is in most tissues, may serve to antagonize Stat1 activity, a theme that was outlined in the preceding sections. (Sects.4.3.1 and 4.3.3). In contrast, the IFN-I dependent activation

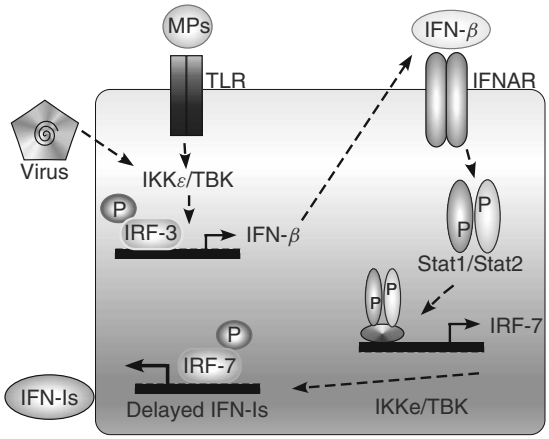

Fig. 5 IFN-I autocrine/paracrine loop. Viral and bacterial pathogens include molecular patterns (MPs) that are recognized by toll-like receptors (TLRs). Once bound to these receptors, they promote the activation of IKKε/TBK1 kinases, which in turn phosphorylate IRF-3. Activated IRF-3 then drives the expression and secretion of IFN-β, an immediate early IFN-I. IFN-β binds the IFN-α receptor (IFNAR) initiating an important autocrine loop. This leads to the expression of IRF-7, an important ISGF-3 target gene, which is responsible for driving the expression/secretion of the delayed IFN-Is.

of Stat4 is limited to leukocytes, where it appears to play an important role in promoting the expression of IFN-γ.

5.1.2 Type II IFN Receptor

There is only one ligand that binds to the type II IFN receptor, IFN-γ. In contrast to the type I IFNs, the gene encoding IFN-γ consists of three exons and resides in a distinct locus. The type II IFN receptor, which is usually referred to as the IFN-γ *receptor*, consists of two CRF2 chains, IFNGR1 and IFNGR2. They associate with Jak1 and Jak2 respectively. In contrast to type I IFNs, IFN-γ secretion is largely restricted to T cells and NK cells, underscoring the need to carefully regulate the activity of this potent proinflammatory cytokine. In T cells, IFN-γ is the signature cytokine of effector Th1 cells, which play a critical role in adaptive immunity. However, NK cell dependent IFN-γ production assures an important role in innate immunity as well. As outlined in Fig. 2, upon binding, ligand two receptor associated JAKs are activated by transphosphorylation, whereupon IFNGR1 becomes phosphorylated on a single tyrosine residue that specifically serves to recruit Stat1 to the receptor complex. Stat1 is activated at the receptor, dimerizes, translocates to the nucleus, and directly binds GAS elements to drive the expression of target genes. Notable GAS-driven target genes include chemokines and transcription regulators. One such transcription regulator is IRF-1, which then directs the expression of ISRE-driven genes, accounting for some of the functional overlap between type I and type II IFNs. Another important transcriptional regulator is CIITA, which coordinates the expression of MHC class II, a signature response associated with IFN-γ stimulation, and is essential for adaptive immunity.

5.1.3 IFN-λ Receptor

The ligands that bind to the IFN-λ receptor are either referred to as λ IFNs or IL-28a, IL28b, and IL-29. Both receptor and ligands were recently identified through genome mining. Although the IFN-λs are functionally quite similar to IFN-Is, they reside in a distinct genomic cluster and are encoded for by multiexon genes, more reminiscent of the gene for IFN-γ. In contrast, the genes encoding IFN-λ receptor chains reside in IFN-I/IL-10 locus (aka CRF2 locus), consisting of CRF2–12 (provisionally named IFN-λR1 or IL-28Rα) and CRF2–4 (a component of the IL-10 receptor; see the following). Although many functional and mechanistic details of this family have not yet been fully elucidated, λ-IFNs do appear to be induced in response to viral infection and predominately signal (at least in fibroblasts) through Stat1–Stat2 heterodimers. The relative role of this unique family during viral or bacterial infections is an area of current investigation.

5.1.4 IL-10 Receptor Family

This family of receptors and their corresponding ligands has grown considerably in size over the last few years. There are five distinct receptor chains that alternatively pair to form at least 5 unique receptors (not including the IFN-λ receptor). They bind and transduce signals for six ligands, including IL-10, IL-19, IL-20, IL-22 (IL-TIF), IL-24 (MDA-7; FISP), and IL-26 (AK-155). IL-10, the founding member of this family, is widely expressed and recognized for its potent and clinically important anti-inflammatory activity. The first evidence that IL-10 might be related to the IFNs came when the sequence of the first IL-10 receptor chain (IL-10R1) was found to be homologous to the IFN-γ receptor. Subsequently, several orphan *CRF2* genes were found to serve as receptors

for IL-10 family members. First was CRF-2–4, identified as the second chain of the IL-10 receptor (IL-10R2). More recently, three additional receptor chains, IL-20R1, IL-20R2, and IL-22R, have been identified. IL-19, IL-20, and IL-24 have been shown to signal through a receptor consisting of IL-20R1 and IL-20R2. However, both IL-20 and IL-24 can also signal through a second receptor consisting of IL-22R and IL-20R2. In contrast, IL-22 appears to signal exclusively through a receptor consisting of IL-22R and IL-10R2, whereas IL-26 appears to signal through a receptor consisting of IL-20R1 and IL-10R2. Of these ligands and receptors, IL-10 and its receptor remain the best characterized. The IL-10 receptor is expressed in most tissues. Its cytoplasmic domains associate with Jak1 and Tyk2 respectively, and serve to recruit and activate Stat3, the same STAT that transduces signals for the gp130 family (Sect. 5.2). Recent studies have provided important insight as to how IL-6 and IL-10 can both transduce signals through Stat3, and yet achieve very different biological responses. It has been determined that because the IL-10 receptor fails to recruit SOCS-3, a potent Stat3 antagonist (see Sect. 6.3), IL-10 directs a significantly prolonged pattern of Stat3 activation, culminating in a distinct pattern of gene expression. In addition, in contrast to gp130 responses (Sects. 4.3.3 and 5.2.1), Stat1 does not appear to play a significant role in directing the biological response to IL-10. With the recent growth in IL-10 like ligands and receptors, much remains to be learned about their biological responses. Initial studies have suggested that IL-19 and IL-20 are preferentially expressed in monocytes, and that IL-20 may play an important role in dermal inflammation. IL-22 has been reported to induce the expression of acute phase response genes in the liver, and IL-24 appears to be a Th2 secreted effector cytokine. Intriguingly, IL-24 appears to selectively antagonize the growth of some tumors. Likewise, IL-26 may also function as a T-cell effector cytokine.

5.2 Extended gp130 Receptor Family

The extended family of gp130 receptors includes a large group of receptors that either employs gp130, or a gp130 homolog as one of their receptor chains. The first, and therefore prototypical member of this family is the receptor for IL-6, consisting of a unique IL-6 ligand-binding chain (IL-6Rα) and gp130. The extended gp130 receptor family can be subdivided into those receptors that are functionally distinct from the IL-6 receptor (i.e. IL-12 family of gp130-related receptors; Sect. 5.2.3) and those that are functionally similar. The latter group can also be further subdivided into two groups, those receptors in which gp130 participates (i.e. IL6-gp130 receptor subfamily; Sect. 5.2.1), and those in which the receptor solely employs gp130 homologs (i.e. gp130-like receptors; Sect. 5.2.2). The discussion of this extended family will start with the prototypical IL6-gp130 receptor subfamily.

5.2.1 IL6-gp130 Receptor Subfamily

gp130 was first identified as the signaling component of the IL-6 receptor. It associates predominantly with Jak2 and encodes four STAT recruitment motifs (referred to as the YXXQ amino acid motifs), which exhibit a differential affinity for Stat1 and Stat3. gp130 also encodes fifth and distinct tyrosine motif (Y759 in mice) that exhibits a unique affinity for SHP2 and SOCS-3. Gene targeting studies creating gp130 chains that either only express a single YXXQ motif

or Y759, have elegantly served to elucidate their roles in mediating the biological response to IL-6. Specifically, the Y759 motif has been shown to direct the activation of an SHP2-MAP kinase signaling cascade that serves to promote cytoprotective (i.e. anti-inflammatory) responses, as well as antagonizing Stat3-dependent signals through the recruitment of SOCS-3. In contrast, YXXQ motifs direct recruitment/activation of Stat3 (and Stat1) to drive the expression of a number of proinflammatory genes, as well as SOCS-3, a Stat3-specific antagonist (Sect. 6.3). These genes are associated with both inflammation and cancer progression. Other IL-6 related ligands that transduce signals through gp130 include, IL-11, CNTF, LIF, OSM, CT-1, NP, and NNT-1/BSF-3. In each case, the corresponding receptors employ a unique chain that either only serves as a ligand-binding chain (like IL-6Rα), or both as a ligand-binding and signal transducing chain. The latter group includes specific receptor chains for OSM (i.e. OSM-Rα) and LIF (i.e. LIF-Rβ), which both exhibit significant homology to gp130. Of note, OSM appears to straddle this and the following group (Sect. 5.2.2), because it binds to two receptors, one that consists of gp130 and OSM-Rα, and the other consisting of OSM-Rα and OSM-Rβ (also a gp130 homolog).

5.2.2 gp130 Receptor-like Subfamily

Although most members of the extended gp130 receptor family include a gp130 chain, several appear to function independent of gp130. As alluded to above, this includes one of the OSM receptors, as well as receptors for IL-31, G-CSF, and Leptin. Curiously, the IL-31 receptor consists of both a unique chain (IL-31Rα) and OSM-Rβ. The receptors for both G-CSF and Leptin function as homodimers (see also section on single-chain receptors). The G-CSF receptor is important for neutrophil maturation, whereas the Leptin receptor is important in weight homeostasis. Importantly however, like in the IL6-gp130 subfamily, each of these ligand–receptor pairs transduces pivotal signals through Stat3.

5.2.3 IL-12 Family of gp130-Related Receptors

This group includes three receptors that are distantly related to, but functionally distinct from the IL-6-gp130 family. They bind to and transduce signals for a unique family of related ligands, which include IL-12, IL-23, IL-27. IL-12, the founding and most fully characterized member of this family is composed of two disulfide-linked peptides of 35 kDa (i.e. p35) and 40 kDa (p40). p35 has homology to IL-6, whereas p40 has homology to the IL-6Rα chain (also IL-11Rα and CNTFRα). p40 can also associate with a distinct 19-kDa subunit (i.e. p19) to form a novel cytokine, IL-23. Another recently identified and more poorly characterized member of this family is IL-27, which consists of EBI3, an IL-12 p40 homolog (recently renamed IL-30), and p28, an IL-12 p35 homolog. Not unexpectedly, this family of related ligands binds to and transduces signals through a family of related receptors. IL-12 binds to a receptor consisting of IL-12Rβ1 and IL-12Rβ2. This receptor is known to direct the sequential activation of Tyk2 and Stat4, both of which have been shown to be important in the biological response to IL-12. The IL-23 receptor consists of the p40 binding IL-12β1 chain and a unique p19 binding chain, now known as IL-23R. Although, one chain of the IL-27 receptor has recently been identified as the orphan WSX-1 receptor chain, the

nature of the second chain and the STAT-dependent signal downstream from this receptor remains controversial. However, the important role these ligands play in regulating the maturation of naïve T cells indicates that their signaling pathways will be similar.

5.3 γC Receptor Family

This family of receptors exploits the common hematopoietic receptor gamma chain (i.e. γC) and plays an important role in directing development and activity of lymphocytes. These receptors can be divided into two functionally distinct subgroups, the IL-2 family and the IL-4 family.

5.3.1 IL-2 Receptor Family

The receptor for IL-2 is a founding member of the cytokine receptor family. The role this receptor and its ligand play in lymphocyte development has been studied extensively. Additional family members that also play an important role in lymphocyte regulation, and their corresponding ligands have been identified over the ensuing years. They include the receptors for IL-7, TSLP, IL-9, IL-15, and IL-21. Each receptor consists of a ligand specific chain (the α-chain) and the common gamma chain (γC). In most cases, α-chains are associated with Jak1 and serve to recruit and mediate the activation of Stat5. The γC, whose expression is limited to hematopoietic tissues, serves to bring Jak3 to the receptor complex. The critical role these latter two components play in lymphocyte function is underscored by the severe combined immunodeficiency (SCID) phenotype that develops when γC or Jak3 are defective. The IL-2 family exhibits a number of additional noteworthy features. First, two closely related members of this receptor family (i.e. the IL-2 and IL-15 receptors) employ a third receptor chain, the β-chain, which serves as the signal transducing chain. In the absence of the α-chain, this β-chain directs the activity of a low affinity IL-2 receptor. Also, the receptor for TSLP does not use γC, rather, it consists of the IL-7R α-chain and a unique TSLP receptor chain. Finally, as mentioned to earlier, each of these receptors, except perhaps the IL-21 receptor, rely on Stat5 to transduce important ligand specific signals.

5.3.2 IL-4 Receptor Family

The receptors for IL-4 and IL-13 consist of an overlapping set of chains and are functionally distinct in the IL-2 family. These receptors and their corresponding ligands have received considerable attention for the role they play in regulating humeral immunity and allergic response. IL-4 binds two distinct receptors. One is composed of the IL-4 receptor α-chain (IL-4Rα), which associates with Jak1, and γC chain, which is associated with Jak3. The second receptor is a heterodimer between IL-4Rα (associated with Jak1) and the IL-13 receptor α-chain (IL-13Rα), which associates with Tyk2. IL-13 binds and signals through the second of these two receptors (i.e. IL-4Rα and IL-13Rα). For both receptors, the IL-4Rα chain serves as the signaling chain, directing the recruitment and activation of Stat6. This, along with the ability to signal through IRS adaptor proteins, functionally distinguishes this family from the IL-2 family. While this small family has overlapping function, gene targeting studies have identified important differences. IL-4 plays a more important role in lymphocyte maturation, whereas IL-13 is more important in directing lymphocyte effector functions.

5.4 IL-3 Receptor Family

The IL-3 family includes receptors for IL-3, IL-5, and GM-CSF (granulocyte macrophage-colony-stimulating factor), all of which play important roles in the development of myeloid lineages. The IL-3 and GM-CSF receptors, and their corresponding ligands, play a more important general role, directing development of granulocytes, macrophages, and dendritic cells (DCs). IL-5 and its receptor appear more specialized, promoting the development of mast cells and eosinophils. Each receptor in this family is composed of two chains: a ligand specific α-chain (i.e. IL-3Rα, IL-5Rα, and GM-CSFRα); and a shared signal transducing β-chain (i.e. β_{common}). The α-chains associate with Jak1 and the β-chain associates with Jak2. The β-chain also serves to recruit and activate Stat5. In mice, however, the receptor for IL-3 is a bit more complex. There are two functionally homologous IL-3 receptor β-chains, β_{IL3} and β_{common}. Analogous to human system, β_{common} serves as the β-chain for GM-CSF and IL-5 receptors, as well as some IL-3 receptors. But the remaining IL-3 receptors employ β_{IL3}, providing redundancy in the ability to respond to IL-3.

5.5 Single-chain Receptor Family

The single-chain receptors are the final family of structurally and functionally related hematopoietin receptors. As their name suggests, these receptors consist of a single chain that both binds ligand and transduces signals. Members of this family include receptors for traditional hematopoietins, like Epo (erythropoietin) and Tpo (thrombopoietin), as well as the receptors for GH and PRL (prolactin). In each case, the ligand binds to and activates a receptor homodimer, culminating in the sequential activation of receptor associated Jak2 and then Stat5. It is worth noting that two receptors from the gp130-related family, the G-CSF and Leptin receptors also function as homodimers.

5.6 Noncytokine Receptors

A number of receptors that are not from the cytokine family also appear to direct a subset of signals through STAT activation. Well-known examples include several receptor tyrosine kinases (RTks), like the receptors for EGF (epidermal growth factor), PDGF (platelet-derived growth factor), FGF (fibroblast growth factor) and potentially Flt3. There are also numerous reports implicating STAT signaling in the response to G proteins and G-protein-coupled receptors. The best-characterized example is the receptor for Angiotensin II (i.e. AT_1). This should not be surprising, since some of the receptors implicated in STAT activation in *Dictyostelium* are G-protein-coupled receptors.

6 Regulation of JAK-STAT Signaling

Two characteristic features of the JAK-STAT signals are their rapid onset and transient nature. With respect to rapid onset, STATs are briskly activated at the receptor, whereupon they quickly translocate to the nucleus and bind DNA. Like for many other nuclear proteins, the process of nuclear import is dependent on a well-characterized set of proteins. Within a period of hours, however, the cytokine stimulated signals decay and the STATs are reexported back to the cytoplasm, resetting the cell for its next round of

stimulation. This signal decay entails both downregulation of the upstream signaling components (i.e. the receptors and JAKs), as well as terminating STAT transcription activity. This section will quickly review three mechanisms that are known to play an important role in STAT signal decay: dephosphorylation, active nuclear export, and inhibition by members of the SOCS family of regulators.

6.1 Phosphatases

It is not surprising that several phosphatases, which regulate all kinase-based signals, have been implicated in the control of STAT signal transduction. Genetic and biochemical approaches have been exploited to identify several cytoplasmic phosphatases that promote the decay of activated cytokine receptors and potentially JAKs. They include SHP-1, SHP-2 and potentially CD45. In contrast, studies directed at characterizing the decay of activated STATs have suggested that STATs are dephosphorylated in the nucleus prior to nuclear export. Although TC-PTP has been implicated as a STAT nuclear phosphatase, it is likely that other STAT phosphatases remain to be identified.

6.2 Nuclear Export

Within hours of having accumulated in the nucleus, STATs are dephosphorylated and reexported back to the cytoplasm, resetting the cell for the next round of stimulation. The process of nuclear export, just like that of nuclear import, is dependent on Ran-GTPases, but the sensitivity of export to leptomycin B has greatly facilitated the analysis of the export process. As expected, leptomycin B has been shown to effectively block poststimulation nuclear export. Unexpectedly however, treatment of resting cells with leptomycin B also promotes STAT nuclear accumulation. This observation highlights an intriguing aspect of STAT biology, not only are STATs rapidly translocated into and out of the nucleus in response to activation, but they also shuttle into and out of the nucleus in resting cells. Moreover, this process is independent of tyrosine phosphorylation! Thus, the predominately cytoplasmic localization of STATs in resting cells represents a steady state balance between nuclear import and export. While the reason for this continuous flux has not been elucidated, distinct nuclear export sequence (NES) elements, which direct either poststimulation or basal nuclear export, have been identified. The distribution of NES elements suggests that their activity (i.e. access to nuclear export machinery) is regulated by conformational changes STATs undergo as they become activated, bind DNA, and then become dephosphorylated.

6.3 The SOCS Family

The SOCS proteins were identified as a family of STAT target genes that directly antagonize STAT activation, establishing a classic ''feedback loop.'' CIS-1 (cytokine-inducible SH2 containing protein), the founding member, was identified as an Epo induced, Stat5 dependent target gene that blocked subsequent Stat5 recruitment to the Epo receptor. SOCS-1 was identified next through several approaches. Comparison of the CIS-1 and SOCS-1 sequences identified a conserved SH2 domain and SOCS box, now recognized as characteristic features of this family. Subsequent gene targeting studies determined that SOCS-1 knockout mice die perinatally from a

profound IFN-γ – Stat1 dependent inflammatory process, underscoring a critical role for SOCS-1 regulating these potent cytokine. In contrast, SOCS-2 has been shown to antagonize the ability of GH to activate Stat5. Consistent with this, the SOCS-2 knockout mice develop gigantism. The final SOCS protein found to regulate cytokine activity is SOCS-3. (SOCS4-7 appear to regulate responses to different classes of stimuli.) Careful studies have determined that SOCS-3 is a Stat3 antagonist. Furthermore, its specificity for IL-6 dependent Stat3 activation appears to be the major determinant in distinguishing between the differing Stat3 dependent responses to IL-6 and IL-10. This level of specificity is achieved through a single SOCS-3 recruitment motif found in gp130 receptor chain (i.e. Y759; see Sect. 5.2.1), but not either of the IL-10 receptor chains. An analogous SOCS-2 recruitment motif has been identified in the GH receptor. Finally, the mechanism by which the SOCS proteins regulate STAT signaling appears to entail more than competition for receptor recruitment. A number of studies have determined that the conserved SOCS box promotes association with the elongin B/C complex, which in turn binds an E3-like ubiquitin ligase, cullin-2, to promote proteosome dependent degradation. Thus, SOCS proteins appear to direct the degradation of at least some of the components in the JAK-STAT signaling cascade. The existence of SOCS proteins underscores the need to counterregulate STAT based signals.

7 Concluding Comments

Studies over the last decade have provided an important insight into how members of the JAK and STAT family direct signal transduction for all four-helix-bundle cytokines (i.e. hematopoietins). While much remains to be learned, significant advances in the future are likely to entail the identification of additional molecules that serve to fine tune this signaling cascade, as well as provide an insight into how these signals integrate with other important signaling pathways. Consistent with this prediction, a number of regulatory molecules, whose role in STAT signaling are not yet fully elucidated, have been identified, including, members of the PIAS (protein inhibitors of activated STATs) family, StIP, Nmi, several phosphatases, and several serine kinases. Recent studies, which have highlighted the role covalent modifications play in the regulation of transcription factors, beget the question of whether STAT signaling will also be found to be regulation by acetylation, methylation, SUMOylation, or nitrosylation.

Keywords

Alleles
Variants of genes, alternative forms of a gene that occur at a given location of a chromosome.

Conserved Extended Haplotypes
Relatively large stretches (1.5 Mb or more) of conserved DNA sequence, in which essentially all allelic markers within the genetic region are identical and shared among a relatively large number of unrelated individuals (typically, although not definitively, greater than or equal to 0.5% of a given population). Operationally, human MHC CEHs are identified by identical markers on a single chromosome at *HLA-B*, complotype and *HLA-DRB1*.

Disease Association
Genetic markers significantly associated with diseases.

Fragments of Conserved Extended Haplotypes
Genetic regions with different sizes of DNA blocks.

genes
Self-reproducing hereditary characters involved in production of proteins.

Genetic Recombination and Hotspots
Points of crossing-over between chromosomes during meiosis determined by family studies. Meiosis is the creation of sex cells by replication of chromosomes followed by

cell division and production of gametes; sperms and eggs. Hotspots refer to hypothetical chromosomal regions with higher rates of recombination.

Genetic Stratification and Population Admixture
Studies of DNA, RNA, or proteins that characterize different nationalities or races.

HLA Polymorphism
Allelic or specificity variation within specific genes or loci of the human MHC.

Human Genetic Diversity
Genetic markers that differ among individuals.

Linkage
Alleles on the same chromosome close enough to be inherited together.

Linkage Disequilibrium
Nonrandom association of inherited alleles in a population.

Major Histocompatibility Complex (MHC)
Polymorphic genes located in the human chromosome 6 involved in immune responses and in transplantation.

Population Genetics
Genetic differences among individuals of different nationalities or racial groups.

We describe genetically fixed segments of DNA within the major histocompatibility complex (MHC) extending to 3.2 Mb of DNA from *HLA-A* to *HLA-DPB1*. These are variable sized DNA fragments that vary in frequency in different ethnicities or races. Within the region, one 1.5-Mb block is relatively frequent, the DNA conserved extended haplotypes (CEHs). These span from *HLA-Cw*, *B* to *HLA-DRB1*, *DQB1* and include the polymorphisms of complement genes (complotypes) and TNF (tumor necrosis factor genes). This segment is informative for mapping disease susceptibility, immune responses, and allotransplantation matching. Other chromosomal regions (paralogous) have conserved genes, including those genetically related to those of the MHC, which also form DNA blocks that could be involved in immune functions and show disease association. DNA blocks can be used to measure human diversity. For example, the aggregate frequency of DNA blocks (ABF), determine the degree of genetic diversity in different populations; Africans, Asians, and Hispanics have higher genetic diversity than Caucasian Americans. The use of single nucleotide polymorphisms (SNPs) to determine DNA blocks (by measurement of linkage disequilibrium (LD)) is limited when ignoring the well-documented variability of frequency and size of DNA blocks among different populations.

1 Introduction

Recent interest in mapping human disease genes using single nucleotide polymorphisms (SNPs) has prompted us to review the structure of the human major histocompatibility complex (MHC) in order to discuss the limitations of such methods. SNPs occur every 200 to 2000 bp of human genomic DNA, and groups of relatively nearby SNPs have been analyzed as haplotypes on the basis of the measurement of linkage disequilibrium (LD). Genetic variation is nonrandomly distributed in the genome, and SNP density and distribution varies. The haplotypes deduced are said to be islands of nucleotide segments that are stable and form blocks. Claims are also made that meiotic crossing-over occurred between these blocks at what are called "hotspots" with the assumption that historic recombinations between the blocks explain and define operationally such blocks. Thus defined, the sizes of such blocks, using LD measurements, are between 5 to approximately 200 kb in size or more than 800 kb. A major drawback of all these reports of SNP blocks is that they disregard the well-documented existence and analysis of DNA blocks in the MHC, which vary in size among individuals and vary in frequency in different ethnicities.

We summarized in two previous reports some of the structural elements and polymorphic character of the human MHC regions between *HLA-A* and *HLA-B*, and between *HLA-B* and *HLA-DRB1*. These two regions have comparable sizes: 1460 kb from *HLA-A* to *HLA-B* and 1375 kb from *HLA-B* to *HLA-DRB1*. We also described the existence of small blocks and other relatively fixed genetic fragments in the human MHC: A/Cw = 1365 kb, Cw/B = 95 kb, TNF region ≥ 7 kb, complotype = 120 kb, and DR/DQ = 150 kb. We used the known frequencies of the latter four different small blocks to deduce the frequencies of common MHC haplotypes with sizes up to 3.4 Mb. We described a model using those four blocks for studying the population-based structure of the MHC with 16 potential kinds of block combinations that are either fragments of or individual blocks of conserved extended haplotypes (CEHs) with a total length of 1470 kb. This segment of the MHC (from *HLA-Cw* to *HLA-DQB1*) has been studied more extensively than the segment between *HLA-A* and *HLA-B* despite the fact that the latter was discovered much earlier.

MHC haplotype blocks and the larger CEHs are usually inherited intact as a unit, and the allele frequency distribution of particular MHC locus combinations in individuals is nonrandom. Specific alleles at various MHC loci tend to occur together on the same chromosome much more or much less frequently than the product of their individual frequencies. The LD between *HLA-A* and *HLA-B* and between *HLA-B* and *HLA-DRB1* has been well determined in some populations. By contrast, recent studies describing "blocks" of conserved DNA sequence (15–150 kb) within the human genome separated by sites of recombination (deduced) based on LD analysis of SNPs, suggest the existence of uniform lengths of conserved DNA sequences. Some investigators believe that each of these short blocks can be studied with high-throughput screening without the need for doing pedigree analysis. This, however, has questionable utility in the MHC. Of interest is a related SNP approach, analyzing a larger stretch of DNA (3.5 Mb) within the MHC, which was

reported recently, with the finding of what were called *surrogate haplotypes* arbitrarily anchored at *HLA-B*. Unfortunately, the haplotypes found did not always correlate with well-defined common haplotypes and CEHs found by pedigree analysis.

The small blocks of the MHC have different sizes and their variants differ in frequency in populations where they behave as fixed genetic units. These genetic units have been used as markers of human diversity, of ethnicity and/or nationality, of immune response, and of disease risk. They can also be used for genetic stratification studies to confirm the similarity or degree of admixture of populations. The HLA-Cw/B, complotype, and DR/DQ small blocks and the larger CEHs or common MHC haplotypes are important, because some of their variants are ethnic specific, while others are shared between different ethnicities. By contrast, SNP analysis in its infancy has rarely been used to distinguish individual variations in and to identify the population-specific distribution of the sizes of conserved DNA sequence longer than that of the small blocks. Furthermore, little effort has been made to understand the discrepancies between measurements of SNP LD as compared with methods of direct counting of different sizes of blocks in the MHC. Our view is that a thorough understanding of the relatively well-characterized MHC blocks in different human populations should serve investigators to better understand the sizes of DNA blocks throughout the genome.

2 The Major Histocompatibility Complex (MHC)

The human MHC is located within chromosomal region 6p21.3, spans at least 3.4 Mb of DNA and contains many genes and pseudogenes. In addition to the classical HLA genes, the MHC contains more than 140 other functional genes, many of which have immune function. The MHC genes are divided into three regions (class I, II, and III). The class I region is located at the telomeric end of the MHC, while the class II is at the centromeric end, with the class III region located between the class I and class II regions (Fig. 1). HLA allelic variants were first studied using serological reagents detecting human HLA

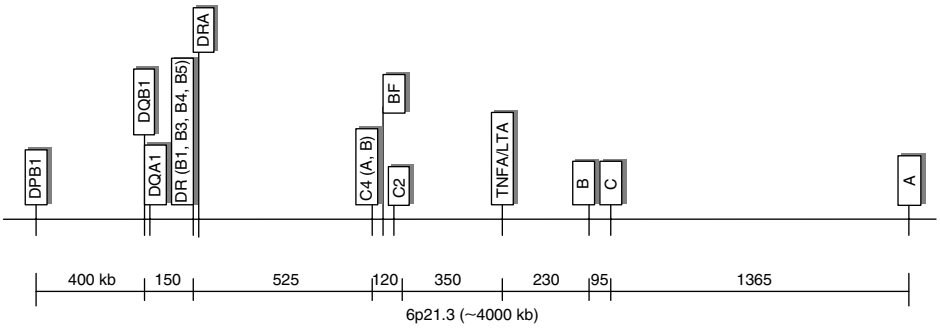

Fig. 1 Map of the human major histocompatibility complex (MHC) in 6p21.3. The physical distances between specific loci are shown. Distances are approximate and vary at many locations in different haplotypes as a result of various DNA insertions, deletions, and gene duplications. Modified from Yunis, E.J. et al. (2003) *Tissue Antigens*.

specificities, but HLA alleles can only be determined with precision using DNA methods. Genetic variants (alleles) at more than one locus inherited together on a parental chromosome are referred to as *haplotypes*.

MHC haplotypes (a term derived from haploid cells) found in an individual can only be defined by pedigree analysis in family studies, but several studies of large populations of unrelated subjects have been published that predicted frequencies of haplotypes calculated by statistical analysis. The original description of an HLA haplotype in 1967 using genotyped data that was obtained by pedigree analysis explained the coinheritance of alleles of two closely linked loci in several unrelated individuals. The concept of LD refers to the nonrandom association between alleles (usually at relatively nearby genetic loci). Therefore, this analytical method was quickly exploited to analyze preferential association between alleles at two or more loci based solely on phenotypic data (i.e. HLA typing of unrelated individuals, in which haplotype phase is not accurately known) has been described for the HLA region by several authors. LD has been an important tool since its early description for the genetic analysis of the human MHC, but the choice of methods for defining LD can be problematic. LD is defined as the difference between the predicted and observed haplotype frequency of specific alleles at two or more loci.

The alleles *A* and *B* at two randomly associated loci having frequencies *f(A)* and *f(B)* should occur together on the same chromosome with a haplotype frequency of $f(AB) = f(A) \times f(B)$. If this condition is not met, the alleles are said to be nonrandomly associated and the departure from prediction indicates the degree to which the alleles are in LD. The pattern of LD in the human genome varies between genomic regions and within a given genomic region between different ethnic groups. LD analysis has played an important role in both gene mapping and as one approach to identifying susceptibility markers in complex diseases. The extent of LD is given by delta $(D) = f(AB) - (f(A) \times f(B))$, where larger delta values indicate greater LD. Thus, the LD of a two-locus haplotype, *AiBj* will be: $LD\ \ (AiBj) = HF(AiBj) - (f(Ai) \times f(Bj))$, where *HF* is the haplotype frequency and *f(Ai)* and *f(Bj)* are the frequencies of the *Ai* and *Bj* alleles. The standard delta value (*D*) is related to the frequency of alleles (*f(A)* and *f(B)*). The allele frequency effect can be partially compensated by calculating a normalized LD value (D') that reflects the relative LD irrespective of allele frequencies. D' is calculated as: $D' = D/Dmax$, where *Dmax* is the maximum *D* value possible. The definition of ''strong'' LD varies by the specific type of locus analysis under study. The highly polymorphic classical MHC haplotypes (and even their small blocks) containing alleles in strong LD generally have a $D' > 0.10$. For statistical tests of the significance, chi-square values are calculated using 2×2 contingency tables converted to *p* values.

LD determinations between *HLA-A* and *HLA-B* and between *HLA-B* and *HLA-DRB1* have been well described. Despite the opportunity for genetic recombination within the MHC seen in human sperm, the effect of meiotic recombination on the population distribution of MHC haplotypes is still uncertain. For example, an apparent ''hotspot'' of genetic recombination was found in human sperm within the class III region of the MHC near *LTA*, whereas a lower than expected recombination rate

was seen between *HLA-A* and *HLA-B*. This would suggest less relative fixity between *HLA-Cw* and *HLA-DRB1* as compared with the class I region. Nevertheless, this recombination site has not been confirmed in family studies. In the absence of both consistent family study confirmation and studies of the effect of sperm recombination on fertilization success and on pregnancy outcome, sperm recombination studies should not be generalized to describe the effect of recombination on haplotype frequencies in the population. Furthermore, the existence of CEHs, found in family studies, within the region between *HLA-Cw* and *HLA-DRB1* (often without a frequent *HLA-A* allele) and the comparable LD between *HLA-A* and *HLA-B* alleles as compared with that between *HLA-B* and *HLA-DRB1* alleles suggests that the genetic fixity of the two regions is similar.

We believe that it is necessary to study more intensively the genetic region between *HLA-Cw* and *HLA-A* to define new class I blocks and to analyze the possibility that the hotspots or regions of historical recombination represent small block boundaries. Recently, other recombination hotspots have been described. However, some of the described hotspots need to be confirmed with finer methods to establish their precise position. The physical distances for the two regions, HLA-A to HLA-Cw/B and HLA-Cw/B to HLA-DR/DQ are nearly identical. Pedigree analyses by family study have shown that both regions have approximately 1% recombination frequencies. If hotspots of genetic recombination between *HLA-B* and *HLA-DRB1* had a significant effect on the population frequencies of specific haplotypes, one would not have expected that the degree of nonrandom association would be higher in the latter. The full extent of LD within the MHC was further demonstrated with the elucidation of genetic polymorphism in the class III region intermediate between *HLA-B* and *HLA-DRB1*. Class III region genes include the complement genes *C2*, *C4A*, *C4B*, and *BF* as well as the cytokine genes *TNF*, *LTA*, and *LTB*. The haplotypes formed by complement genes in MHC class III region are called *complotypes* [K]. There are 14 relatively high-frequency complotypes in Caucasians that occur with a combined frequency of 0.96. MHC haplotypes defined by pedigree analysis containing essentially fixed DNA sequence across class I, II, and III loci found at relatively high frequency in specific populations are referred to as *CEHs* or *ancestral haplotypes* (AHs).

The presence in the population of CEHs, each defined by pedigree analysis, provides evidence for the DNA fixity in specific haplotypes of unrelated individuals. Two recent studies using LD analysis failed to find a significant amount of nonrandom association within the *HLA-Cw* to *HLA-DRB1* region other than in small blocks, although a third study found such associations. The former results are in apparent conflict with those reported by us and by others. We are not surprised that statistical analyses of a relatively few haplotypes (or unrelated individuals) fail to detect more than a few nonrandom associations of alleles of the MHC.

Reports describing the existence of ''blocks'' of conserved DNA sequence in the range of 5 to 150 kb within the human genome, separated by sites of high recombination activity, are based solely on LD analysis applied to SNP data. Most of these reports have concluded that such blocks represent relatively uniform lengths of conserved DNA sequences maintained throughout the human population as haplotypes. Many investigators now believe that such short blocks can be studied

with high-throughput screening without pedigree analysis. Although these techniques have been used recently to detect some of the previously demonstrated associations in the already well-characterized MHC genes and variants, their current utility, at least within the MHC, is uncertain. For example, LD analysis of SNP typing results, from unrelated Caucasian donors, was used recently across a much longer stretch of DNA (3.5 Mb) within the MHC to study "surrogate" *HLA-B* haplotypes. Genetic fixity within the MHC is so great that even LD measurements, taken over long distances of computer-constructed surrogate haplotypes (i.e. not defined by pedigree analysis) predicted to varying degrees the existence of specific common MHC haplotypes, although the haplotypes predicted often did not conform to high-frequency haplotypes seen in larger population studies based on direct haplotype counting through pedigree analysis. Another report, using pedigree-defined SNP-typed MHC haplotypes to construct an "integrated haplotype map" of the MHC, claimed that genetic fixity is higher within the MHC than throughout the rest of the human genome. However, those results did not achieve statistical significance, and the report only identified one common haplotype (although shorter) found in larger haplotype studies. SNP haplotype analysis, in its infancy, clearly still has much to prove before it might be considered a useful method for providing new insights into structure–function relationships, at least within the already well-characterized MHC.

2.1 MHC Blocks

A block size range of 5 to 150 kb in the human MHC have been well defined. These blocks are different from those recently reported, are never characterized solely by SNP typing, are highly polymorphic, and are diverse in different ethnic groups. Specific MHC blocks with specific alleles of one locus are often "haplospecific" for particular CEHs. Frequently, one allele at one MHC locus is highly correlated with an entire CEH. In other cases, a specific group of alleles within the same MHC block or in separate blocks is required to have a high correlation with a specific CEH. However, definitive characterization of haplotypes requires the analysis of families. Some haplotypes are not CEHs but could contain fragments or small blocks from specific CEHs. The best determination of haplotypes would require family studies.

2.2 HLA Blocks

In previous reports, we have summarized the two best characterized blocks of HLA loci, but we will emphasize in the following that the frequency distribution of the inheritance of the two blocks together has not been done in a critical manner. Instead, it has been possible to deduce the resulting haplotypes for the purpose of comparing frequencies of blocks and haplotypes in several ethnicities.

2.2.1 HLA-Cw/B Block

The HLA-Cw/B block is a relatively small segment of DNA (95 kb in length). Figure 2 shows the most frequent HLA-Cw/B block associations in four different ethnic groups of Americans, which, as reported before, are found in strong ($D' > 0.10$) and significant ($p > 0.0005$) LD. African-Americans, Asian-Americans, and Caucasian Americans share several high-frequency small blocks. Also shown

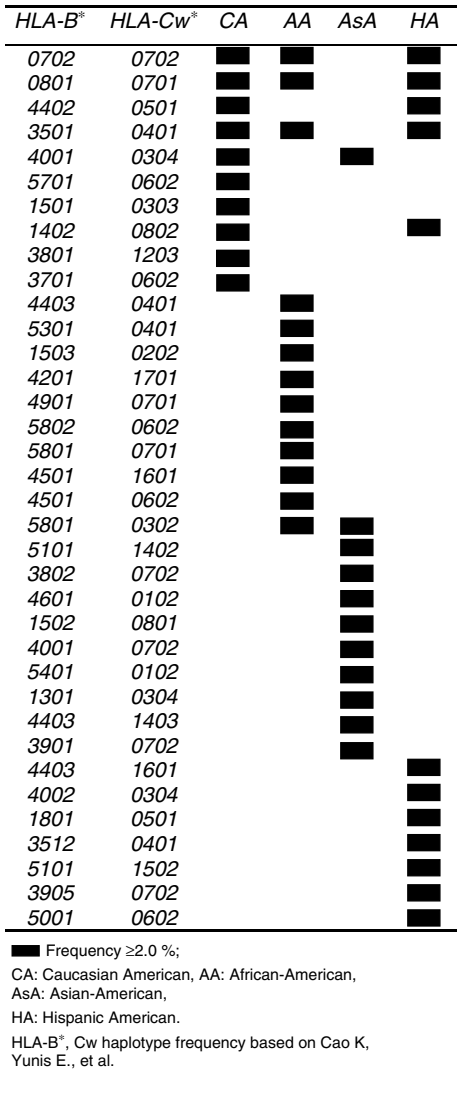

Fig. 2 Common HLA-B*, Cw* haplotypes in different populations.

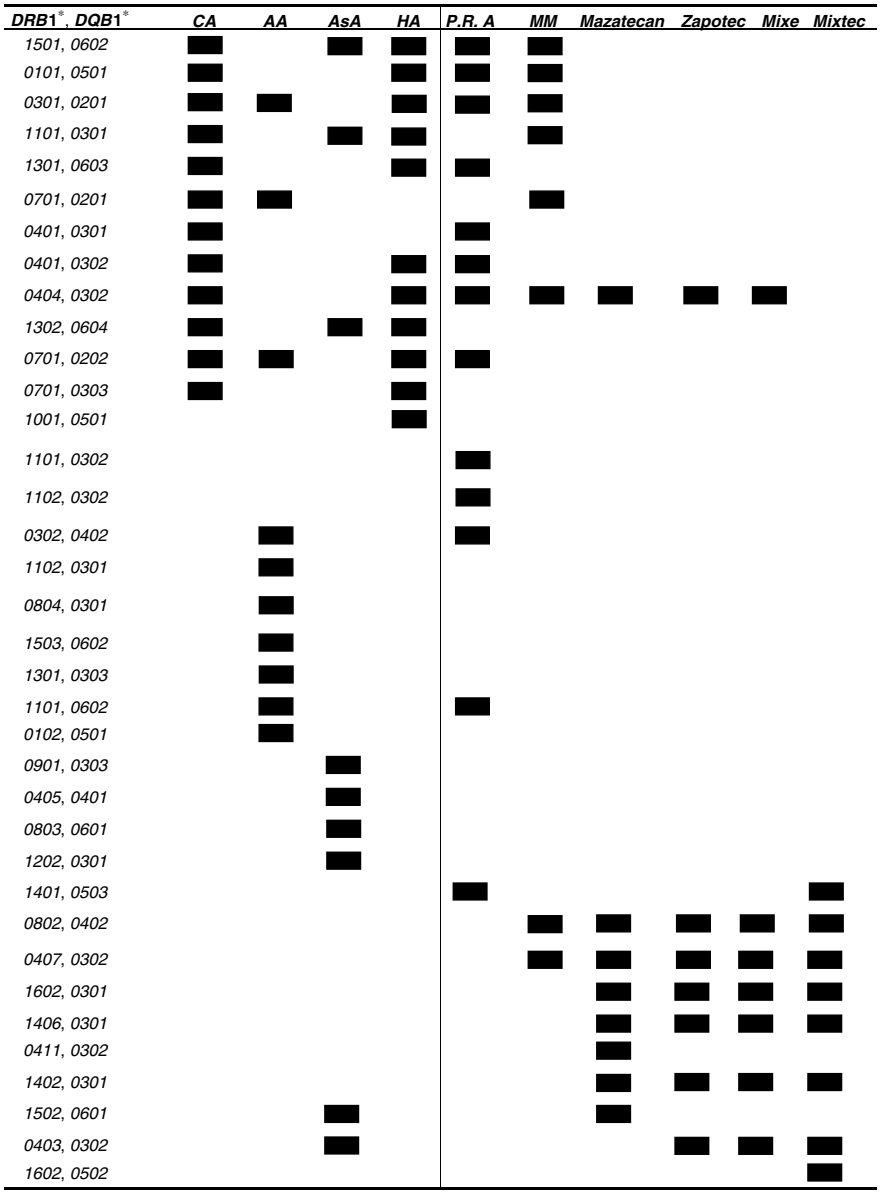
are the frequent HLA-Cw/B blocks of Hispanic Americans to show haplotypes that indicate ethnic admixture. However, some blocks are much more frequently found in only one or two of the groups. Certain blocks are of higher frequency: (*HLA-Cw*0702, B*0702*) ($f = 0.11$), (*HLA-Cw*0701, B*0801*) ($f = 0.11$), and (*HLA-Cw*0502, B*4402*) ($f = 0.09$) in Caucasian Americans; (*HLA-Cw*0401, B*5301*) ($f = 0.09$), (*HLA-Cw*0202, B*1503*) ($f = 0.07$), and (*HLA-Cw*1701, B*4201*) ($f = 0.05$) in African-Americans; and (*HLA-Cw*0302, B*5801*) ($f = 0.07$), (*HLA-Cw*0702, B*3802*) ($f = 0.07$), and (*HLA-Cw*0102, B*4601*) ($f = 0.06$) in Asian-Americans.

2.2.2 HLA-DR/DQ Block

The HLA-DR/DQ region, spanning approximately 150 kb, is the longest of the four MHC blocks. The definition of this block is based on published frequencies of *HLA-DRB1, -DQB1* haplotypes in three different American populations. *HLA-DRB3/4/5* and *-DQA1* are other well-characterized polymorphic loci located within this DNA segment. Figure 3 summarizes the frequency data for the most frequent DR/DQ haplotypes in various ethnic groups. Some of these DR/DQ blocks are found much more frequently in certain ethnic groups. For example, (*HLA-DRB1*0401, DQB1*0301*) is primarily found in Caucasian Americans ($f = 0.03$); (*HLA DRB1*1503, DQB1*0602*) is primarily found in African-Americans ($f = 0.07$); and (*HLA-DRB1*0901, DQB1*0303*) is primarily found in Asian-Americans ($f = 0.10$). Other DR/DQ haplotypes are found frequently in more than one ethnic group. There are also a few haplotypes shared between Americans of all major ethnicities. For North American Hispanics, some of the haplotypes are ethnically specific and probably resulted from admixture with Amerindians. This is easily demonstrated when studying Mexicans, Mexican Americans, or other Hispanic Americans. In such cases the degree of admixture with African, Asian, and Amerindian haplotypes is variable (Fig. 3).



Shared and ethnic-specific DRB1*, DQB1* haplotypes based on Yunis EJ et al. (B, C), Zuñiga J, Azocar J, Yunis EJ (unpublished results P.R.A.), Vargas-Alarcon G et al., Arnaiz-Villena A et al., Hollenbach JA., et al.

Fig. 3 Common *HLA-DRB1**, *DQB1** haplotypes in different populations.

2.3

Common HLA Haplotypes Defined Serologically and Deduced HLA-Cw/B, HLA-DRB1/DQB1 Common Haplotypes and their Frequencies

We previously summarized the frequency distribution of common HLA haplotypes defined by serological specificities for *HLA-A, B,* and *DR*. The allele-level typing of these haplotypes has not been determined systematically in a large database. Figure 4 shows the probable allele-level typing of the most common (serologically defined) HLA haplotypes in four American ethnic groups. The alleles assigned were determined by a combination of deduction and specific studies of individual haplotypes, often found in homozygous cell lines. Not shown in the figure is the fact that there is a large number of Hispanic common haplotypes with a frequency of less than 0.005, which is an indication of the higher genetic diversity of Hispanic Americans.

2.4

The Aggregate Block Frequency (ABF) Measures Genetic Diversity

The sum of frequencies of small blocks, larger blocks, or entire haplotypes within

CA: Caucasian American, AA: African-American, AsA: Asian-American, HA: Hispanic-American.

Frequencies based on Yunis EJ et al., and Cao K et al.

Fig. 4 Common *HLA-A*, B*, Cw*, DRB1*, DQB1** haplotypes in different populations.

the MHC, defined by two or more loci sharing significant LD, is named ABF (*aggregate block frequency*). The frequencies higher than 1% (arbitrarily) of variants of particular blocks are added to compare the degree of diversity of populations studied. It is of interest that the ABFs of individual HLA blocks usually do not show much difference in all ethnicities studied. However, the ABFs of two or more combined blocks show that the Caucasian Americans have less diversity than African- or Asian-Americans. Of interest, the Mexican and Puerto Rican Americans appear to have a higher level of diversity by the use of available information of the DR/DQ block. In preliminary studies, we have determined that the Puerto Rican population of Massachusetts shows a high genetic diversity due to the admixture of Caucasian, African, and Asian haplotypes that are present in frequencies of less than 1%. The ABF for the common haplotypes from *HLA-A* to *HLA-DQB1* is 0.17 in Caucasian Americans, whereas it is 0.03 in African-Americans and 0.10 in Asian-Americans. The ABFs for common haplotypes of Hispanic Americans is approximately 0.06.

2.5 Class III Region Blocks

2.5.1 TNF Block

The shortest conserved MHC block studied is of 7 kb size and contains the genes for TNF-α and TNF-β (lymphotoxin-α). The *TNF* (tumor necrosis factor) microsatellites a, b, and c are upstream (a, b) or within (c) the *LTA* gene. Also, the TNF block includes the SNPs of the *TNF* promoter region. Specific variants of this block are present in all populations while others may be population-specific. Specific variants of this block are also haplospecific. For example, the nucleotide A (substituting for the common G nucleotide) at the −243 position is a marker for the African CEH [*HLA-A*3001, Cw*1701, B*4201, FC(1,90)0, DRB1*0302, DQB1*0402*]. Also, the *TNF* 237(G-A)* SNP is haplospecific for the *HLA-B*4001* CEH found often in Caucasians and for at least some of the *HLA-B48* haplotypes of East Asians found also in Colombian Amerindians. Likewise, a *TNF*-307(G-A), *862(C-A),* and **856(C-T)* combination is found in both Caucasian and Asian haplotypes. It is not surprising that variants of this block are in LD with both complotypes and the HLA-Cw/B block variants.

2.5.2 Complotype Block

The four MHC-encoded complement genes (*C4B, C4A, BF*, and *C2*) are located between *HLA-DRB1* (525-kb centromeric to the complement genes) and *TNF* (350-kb telomeric to the complement genes). This block is variable in length from 75 to 120 kb. The gene order is Telomere-*C2-BF-C4A-CYP21A-C4B-CYP21B*-Centromere. Complotypes are inherited together as a unit, essentially without recombination. The most frequent haplotypes are *SC31* and *FC31* detected in all ethnic groups and *SC01* frequent among the British. Two complotypes are ethnic specific, the *SC21* of the Ashkenazi Jews and the *F1C30* of Basques and Sardinians.

3 Conserved Extended Haplotypes (CEHs)

Family studies have identified MHC haplotypes that show a significant degree of sequence conservation across a large stretch of the MHC in the region between *HLA-Cw, B, TNF, HSP-70*, complotype, and *DR,DQ*. Twelve of the CEHs found in

Caucasians are listed in Fig. 5. For detailed information, consult our earlier reviews.

3.1 Extension of the HLA-Cw/B Block to HLA-A and of the HLA-DR/DQ Block to HLA-DPB1

Figure 4 lists the high-frequency CEHs and common HLA haplotypes that extend to *HLA-A*. Inclusion of *HLA-A* alleles diminishes the ABF. At least four CEHs found in Caucasians extend to the HLA-DP region. Strong LD between the HLA-DR/DQ region and *HLA-DPB1* was shown for several ethnic groups during the 11th international histo compatibility workshop (IHWS), and more recently in Japanese. LD predictions, however, have reported a lack of nonrandom association between HLA-DR/DQ and DP, perhaps reflecting high levels of recombination within this region and/or the inability of statistical analysis to find genetic fixity or nonrandom associations in relatively small databases of haplotypes or unrelated individuals. In Caucasians, the CEH [*HLA-A*0101, Cw*0701, B*0801, SC01, DRB1*0301, DQB1*0201*] frequent in both the British and in Ashkenazi Jews, often extends to *HLA-DPB1*0401*. Also, the CEH [*HLA-A*3002, Cw*0501, B*1801, F1C30, DRB1*0301, DQB1*0201*] of the Basques and Sardinians often extends to *HLA-DPB1*0202*.

3.1.1 Frequency Distribution of MHC Blocks, CEH Fragments, and CEHs

Table 1 shows the frequency distribution of DNA blocks within a region of MHC of approximately 1.5 MB, between *HLA-Cw* and *HLA-DQB1*, in a study of 372 haplotypes determined in 92 pedigree-analyzed Caucasian families. Figure 5, showing the distribution of these haplotypes as analyzed by our previously published model, demonstrates that, of the 12 most frequent Caucasian CEHs, only 9 CEHs show nonrandom association with significant LD (<0.0005). Interestingly, approximately one-third of the haplotypes are composed of combinations of blocks in random association. Therefore, some CEHs cannot be found with statistical significance in this limited database. However, the small HLA-Cw/B and DR/DQ blocks were found to have significant LD corroborating those described previously. These data are the first demonstration of the frequency distribution of blocks in genotyped families ($n = 92$), although the data for complotypes were deduced from previous studies. The ABF measurement is comparable to those that had been deduced by us from separate reports of HLA-Cw/B and DR/DQ blocks. The high frequency of the complotype SC31 explains why CEHs carrying it require a larger database to produce LD to reach statistical significance.

3.1.2 The Global LD Measurement Related to the Size of the Database

As had been reported before, global LD measurements of large size DNA blocks or haplotypes are not informative when the size of the data studied is small. However, there were several small blocks and fragments of CEHs that can be found even with a limited number of haplotypes as demonstrated in the analyses of the data shown in Fig. 5 and Table 1.

3.1.3 Association of CEHs with Disease

Disease susceptibility or protective alleles of particular loci are included in several CEHs or their associated fragments. Important studies of pedigree-analyzed CEHs have been conducted to localize disease susceptibility genes, including type 1 diabetes, IgA deficiency,

[a]Cao, K., Hollenbach, J., Shi, X., Shi, W., Chopek, M., Fernandez-Viña, M.A. (2001) Analysis of the frequencies of *HLA-A*, *B*, and *C* alleles and haplotypes in the five major ethnic groups of the United States reveals high levels of diversity in these loci and contrasting distribution patterns in these populations, *Hum. Immunol.* **62**, 1009–1030.

[b]Modified from Alper, C.A. (1998) Extended MHC haplotypes and disease markers, *ISI Atlas Sci: Immunol.* **1**, 79–83.

[c]Yunis, E.J. et al. (2005).

[d]Complotypes were deduced on the basis of the association between Cw/B, TNF, and complotypes.

The term ''blocks'' was defined as published. LDs were significant between Cw/B and TNF in all 12 kinds of block combinations listed by Roman numerals in Fig. 5. However, only 9 were significant for CEHs (not VII, X, and XI).

dermatitis herpetiformis, and gluten-sensitive enteropathy. Likewise, fragments of the CEH [*HLA-Cw*0303, B*5502, SB45, DRB1*1401, DQB1*0503*] served to map pemphigus vulgaris (PV) genetic susceptibility in non-Jewish patients to the DR, DQ region. But, PV in Jewish patients is associated with the entire Ashkenazi CEH [*HLA-A*2601, Cw*1203, B*3801, SC21, DRB1*0402, DQB1*0302*]. One of the most frequent CEH of Caucasians, [*HLA-A*0301, Cw*0702, B*0702, SC31, DRB1*0501, DQB1*0602*], has been found to be associated with multiple sclerosis (MS) and with ragweed allergy. In another study, we had prior evidence that the CEH [*HLA-B8, SC01, DR3*] was increased among nonresponders to hepatitis B vaccine and that such subjects were more homozygous than expected. We prospectively immunized homozygotes and heterozygotes and none of the homozygotes responded, confirming the dominant role of the MHC in the immune response.

4
Mapping of MHC Disease Genes: New Model for Future Studies Combining Genotyped Individuals with the Use of High-throughput SNPs

Unfortunately, the great genetic fixity of the MHC has prevented formal identification of the true susceptibility gene for any of the diseases described earlier. A more practical approach than simply SNP ''mapping'' the entire MHC would be to genotype at least the four blocks we described and then, as a second step, to analyze more intensively the localized region (small block) most frequently associated with the disease. The ''random'' variants of that small block present in patients would perhaps be more informative than those variants found in the CEHs associated with the disease. In the example described in Fig. 5, one-third of the haplotypes contained only such random small blocks.

5
Paralogous Chromosomal Regions

Paralogous chromosomal regions are those genomic regions found in a single species, which are thought to have a common genetic origin, but which have been separated by mechanisms of duplication from an ancestral genetic unit. Other hypotheses suggest that perhaps independently duplicated genes were grouped during evolution by selective forces. Paralogous genes have been found in different chromosomal segments in humans. The early findings demonstrate the existence in chromosomes 11 and 12 of duplicated chromosomal segments in which two pairs of duplicate genes were contained. In general, the block duplication mechanism can better explain why genes paralogous to some found in the MHC are clustered in three other specific regions of the human genome.

Several published studies have described the existence of three chromosomal regions paralogous to the MHC: 1q21-25, 9q33-34, and 19p13.4–13.1. The possible origin of MHC paralogous regions on chromosomes 1, 9, and 19 could be from two rounds of duplication of the whole genome (2R hypothesis). These findings are supported by the identification of paralogous genes in *Drosophila melanogaster* and in other species in human chromosomes 1, 9, and 19. Phylogenetic analyses have revealed that the MHC and its paralogous regions have a common (ancestral) genomic region that was duplicated as

a block after the divergence of cephalochordates and vertebrates. Duplications (polyploidizations) could have occurred between 766 and 528 Myr ago. Interestingly, the MHC paralogous region in chromosome 9q32-34 retains an ancestral state in the context of organization and gene substitution patterns compared with both the human 1p31-p11, 19p13, and 6p21.3 regions and with the amphibious, chordate, and gnathostomata proto-MHC regions. The MHC paralogous genes are located in the classical MHC class I and class II regions, but also can be found in neighboring regions of the MHC. Gene families such as *NOTCH*, *BRD*, and *PBX* have copies in all of the MHC paralogous regions, but some genes that have paralogous copies in chromosomes 1, 9, and 19 are not found in the MHC.

Among the other previously mentioned paralogous regions, the 1q21-25 is unique because it contains histocompatibility-like loci in the CD1 and MR1 regions. CD1 molecules show structural and functional similarities in relation to HLA class I molecules. The CD1 molecules can present certain glycolipids to cytotoxic T lymphocytes. Genomic sequence of the human chromosome 9 reveals a highly polymorphic structure with a total of 31 genes paralogous to genes found in the human MHC. Interestingly, in chromosome 9, more than 90 genes associated with different human diseases have been mapped. These include *AIF1-L*, *BAT2-L*, *C5*, *PBX3*, *BRD3*, *COL1A5*, and *RXRA*. This fact is important in attempting to decipher the possible influence of several loci in polygenic diseases. Also of interest is that, in the extended MHC class I region of chromosome 6, families of olfactory receptor genes have been mapped also in the chromosome 9 paralogous region. This fact could be a determinant in the species preservation and reproduction, as recent reports suggested that mate selection could be influenced by HLA segregation of specific parental haplotypes that could be in LD with specific olfactory related genes in the proximity of MHC.

6 Discussion

High-resolution definition of the most frequent MHC haplotypes extending from at least *HLA-Cw* to *HLA-DQB1* is incomplete at the phenotype level, much less at the genotype level using pedigree analysis. We summarized the current knowledge of allelic variants of well-studied loci in common HLA haplotypes and, to a limited extent only, in MHC CEHs. Using the frequencies of nonrandomly associated alleles of two close loci, *HLA-Cw, -B* in one example and *HLA-DRB1, -DQB1* in another, we described blocks of DNA measuring approximately 100 to 150 kb each. We deduced that the existence of common HLA haplotypes, defined as the *nonrandom association* of these two blocks, is related to genetic fixity within the MHC spanning at least 1.4 Mb as exemplified by the existence of CEHs. When typing of the intermediate class III region of the MHC (complotypes, TNF, and *HSP-70*) and haplotype identification by pedigree analysis are conducted, approximately 85% of common HLA haplotypes are the same as genetically fixed CEHs. We showed in Fig. 5 that approximately 22% of common HLA haplotypes are not CEHs because the intermediate regions have different degrees of LDs (often related to separate CEH variants).

Although several of the MHC loci are among the most polymorphic known in the human genome, they represent only a small percentage of the total MHC DNA

sequence. Formal proof of the essential fixity of the complete DNA sequence for specific MHC CEHs shall require DNA sequencing of the entire region in several independent examples. This work has begun on consanguineous cell lines, with the MHC Haplotype Project. If one expands the CEH definition to include the loci from *HLA-A* to *HLA-DPB1*, the fixed DNA length would be more than 3 Mb of DNA.

The frequency of block combinations varies between major ethnic groups and/or in different nationalities. The preponderance of common haplotypes in Caucasians may be due to the fact that more Caucasians than Africans or Asians have been studied or may simply reflect a lower genetic diversity among Caucasians. Prediction of individual HLA blocks (e.g. HLA-Cw/B) by LD has been more complete than has identification of larger fragments or CEHs (which include TNF and/or complotype blocks) by family study. Identifying CEHs in a population depends on the size of the haplotype database. Lower frequency CEHs can only be identified in larger databases. It is important to keep in mind that the number of and the particular types of CEHs (or common haplotypes) detected will also depend on the type (e.g. ethnicity, disease status) of the population studied. Some CEHs, such as the first six listed in Table 1 and Fig. 5, are relatively frequent in healthy Caucasians. In a database of 500 Caucasian haplotypes, we would predict the aggregate frequency of all of the CEHs listed in Fig. 5 (not including *HLA-A*) to be at least 30%. In this review, we reported an analysis of 372 haplotypes derived from pedigree analysis of 92 parents, although the complotypes were deduced from probable nonrandom associations using our previous studies. Only nine CEHs showed significant nonrandom associations. The number of individuals studied would also affect the distribution of CEHs, their fragments, and small blocks. The arrows in Fig. 5 suggest sites of possible historical recombination that in many recent articles using SNPs are referred to as *hotspots*.

Structural analysis of MHC haplotypes is incomplete, but we believe that the available evidence demonstrates that there are fixed genetical segments of DNA within the MHC, the frequency of which vary in different human populations. Some CEHs have shown significant genetic fixity across blocks of DNA as large as 3.2 Mb from *HLA-A* to *-DPB1*. However, the most completely described segment spans *HLA-Cw* and *-DQB1*, and includes polymorphisms of complement genes (complotypes) and TNF. The boundaries of this 1.5-Mb block mark CEHs that are relatively frequent, which have proven informative for mapping disease susceptibility and immune response genes and they could be used for allotransplantation matching.

The concept of the aggregate frequency of individual common block variants spanning the MHC segment between HLA-Cw/B and HLA-DR/DQ, or ABF, may be used to determine the degree of relative diversity of Americans of Asian, Caucasian, African, or Hispanic ancestry. Likewise, we suggest that determining the ABF of a combination of small blocks can be used to estimate the degree of genetic fixity of even larger segments of DNA called *common HLA haplotypes* (which are usually representative of CEHs). Thus, ABF is a measurement of the frequency of DNA blocks of any particular size range, based on the aggregate frequency of nonrandomly associated alleles at two or more loci, which estimates the frequency of various sizes of genetically fixed DNA within the MHC of well-defined populations. The

result can be used to compare human diversity among well-defined populations.

Other DNA methods, such as RFLP (restriction fragment length polymorphism), SNP analysis, and microsatellite polymorphisms, have also been useful in defining extended genomic variation throughout the MHC at sites other than the classical HLA loci (e.g. complement and TNF locus typing). Allele-level typing of *HLA-A*, *-Cw*, *-B*, *-DRB1*, and/or *-DQB1* has been reported for a limited number of Americans of different ethnicities. At least three characteristics of these MHC haplotype blocks are quite different from those recently reported. MHC blocks described here are never defined solely by SNP typing and are highly polymorphic within well-characterized populations. In contrast to two to five common SNP-defined haplotype variants present in diverse ethnic groups, MHC blocks have many more common variants even within a single ethnic group. Finally, MHC haplotype variants exhibit a high degree of isolated population and/or ethnic specificity. Furthermore, despite both the likelihood of many recombination ''hotspots'' within the MHC and this great diversity within specific MHC blocks, many CEHs exist at relatively high frequency. Specific alleles or specific MHC blocks are often ''haplospecific'' for particular CEHs. In many cases, one particular allele at one locus is highly correlated with an entire MHC CEH. In other cases, a specific set of alleles within a single MHC block or in more than one block is required to achieve a high correlation with a particular CEH. However, haplotype determination by family study is required to rigorously define a complete haplotype.

Many MHC haplotypes are not CEHs but contain only fragments or even only a single small block from any specific CEH. Non-CEH haplotypes containing CEH fragments are represented in Fig. 5 by any haplotype except #1 (the full CEH) or #16 (containing no part of any CEH). For example, not all haplotypes containing the (*HLA-Cw*0701, B*0801*) block exist solely as the CEH [*HLA-Cw*0701, B*0801, TNF 2,3,1, SC01, DRB1*0301, DQB1*0201*] (although, we argue, the majority are contributed by this CEH). The distribution in frequencies between any given CEH and its specific blocks depends on several factors, including at least the degree to which a particular block exists in more than one extended haplotype (i.e. is not haplospecific) and the degree of fragmentation of the extended haplotype in the study population. If a disease gene is mapped to a CEH, the number of haplotypes bearing fragments of that CEH that is required to localize the gene will be greater than the number of ''random'' haplotypes required. If the gene is already mapped to a small block, variants of that block that are not associated with any CEH required to localize the gene should be fewer, because the complete set of these ''random'' variants should share little that is unique except for the susceptibility locus. For these reasons, it is probably more difficult to map susceptibility genes in American Caucasians than in other American ethnicities simply because the level of genetic diversity is lower in Caucasian Americans. We also believe that most of the diversity is possibly related to the degree of genetic admixture of individuals recruited, and this admixture could be within nationalities or between ethnicities.

An example of this complexity can be the use of the term Hispanic to describe individuals that originated from Spanish-speaking countries. Of course, such individuals probably resulted from different degrees of population admixture

producing stratification, and they represent many different ethnicities. The use of SNPs or short tandem repeats or variants of genes that could have been conserved in all humans or within a particular ethnicity will need to be used to rule out population genetic stratification in every study population. In this case, DNA blocks that are conserved in the genome need to be identified in order to distinguish them from DNA blocks that show variability caused by population admixture or by natural selection.

CEHs might result from many possible mechanisms, including recent population bottlenecks, recombination suppression, preferential transmission, migration and admixture, and/or genetic drift or natural selection. Duplication of genes involved in immune functions argues in favor of selection for blocks of DNA, which vary in different populations. Paralogous genes to some found in the human MHC with equal or related functions are located in other chromosomes (Chromosomes 1, 9, and 19). Such duplicated genes add another dimension of difficulty to disease gene localization because there may be several genes involved in a disease, which are molecularly related. For example, the *NOTCH* genes are found in the four paralogous chromosomal regions. One caveat, however, is that the MHC paralogous region of chromosome 9 contains many other genes that may be in LD with *NOTCH1*, but the equivalent genes to those are not present in chromosome 6. In the case of schizophrenia, *NOTCH4* could be in LD with another marker different from that of *NOTCH1* and it could suggest a difference in the populations studied. However, the *BRD2* and *BRD3* genes of chromosomes 6 and 9, respectively, are at similar distances to the *C4* genes of chromosome 6 and the *C5* of chromosome 9. The latter region is expected to have genes in LD that may be acting synergistically.

7 Future Studies

Complete human population studies based on the CEH and DNA blocks concept are needed. Requirements will include collecting data on the basis of geography (nationality), language, and ethnicity, as well as identifying other (non-MHC) genetic markers. The latter include the Y chromosome, mitochondrial DNA, blood groups, and short tandem repeats outside the MHC region. Such analysis could derive the age of haplotypes and population diversity relationships. Genetic admixtures need to be analyzed in order to know the markers that indicate genetic drifts or old admixtures. We believe that any unique marker of the polymorphic loci of a haplotype would be a marker of the age of the MHC haplotype. Two or more ancient mutations or gene conversions inherited together will have random frequencies, but during evolution they are fixed at the population level and may prove to have selective advantage. Natural selection is often mentioned as a major influence in MHC evolution and in the formation of CEH. However, nonrandom association between distant loci may be the result of directional selection (molecular cooperation during the immune response). In this context, the possible role of paralogous genes may be operating. Alternatively, balancing selection by a higher replacement rate of different alleles at certain loci could have been an influence, particularly a departure from neutral expectation of HLA frequencies.

8 Summary

We described an updated interpretation or definition of MHC or HLA haplotypes. Although the information is incomplete, we believe that there are genetically fixed MHC haplotypes of variable sizes in the human population and that the stretch of fixed DNA could be up to 3.2 Mb of DNA in several haplotypes that extend from *HLA-A* to *HLA-DPB1*. However, the fixity of the DNA between *HLA-Cw* and *HLA-DQB1* has been studied more extensively, using polymorphisms of the complement system (complotype) and the TNF region to define that stretch of fixed DNA of approximately 1.5 Mb. The boundaries of this large block, between *HLA-Cw* and *HLA-DQ*, mark MHC CEHs with fixed (or nearly so) DNA that are relatively frequent and have been used for mapping studies of disease and immune responses, and they could be used for matching for allotransplantation. The aggregate block frequencies (ABFs) of both the HLA-Cw/B and HLA-DRB1/DQB1 small blocks were investigated in three different ethnic groups living in the United States and in five African populations. The results suggest that the aggregate frequency of the most common small blocks in strong and significant LD may be used to determine the degree of relative diversity of Asian, Caucasian, or African-Americans and Hispanic populations. Likewise, we suggest that determining the ABF of a combination of specific small blocks can be used to determine the degree of genetic fixity of even larger segments of DNA. Thus, ABF is a measurement of the total frequency of fixed genetic (high population frequency) variants of a particular DNA block, to estimate the frequency of various sizes of DNA within the MHC of well-defined populations. This measurement adds a new dimension in the studies of human diversity. Essentially, we have developed a model of combinations of blocks of 16 kinds of MHC haplotypes, with one of them being the CEH, seven of them being CEH fragments containing combinations of the CEH blocks, seven more having only one CEH block or two separated blocks, and one of them containing only rare blocks that do not show any LD. We used as an example the higher degree of genetic diversity of the Mexican Mestizos as compared with Caucasian Americans or specific Amerindian subgroups to demonstrate that diversity as measured by ABF can vary related to the contribution of the genetic diversity of the populations that contributed to a particular population admixture. We anticipate that genetic diversity will also differ between supposedly ethnically similar individuals when they are recruited from different geographic regions. Although not defined in the same manner, as recently reported blocks of SNPs, previously identified MHC blocks are essentially genetic units. We discussed the problem of attempting to use SNP blocks to localize disease genes without previous assignment of MHC blocks determined by high-resolution typing and preferably by pedigree analysis. We suggest that after this is done, it is possible to map disease or protection genes using positional cloning and high-throughput technologies. Disease genes could be located in either large or small blocks of DNA, but we believe that it will be easier to look for them in random blocks not associated with high-frequency CEHs. We also discussed the possibility of applying the techniques and analytical methodologies developed for the MHC to other chromosomes of the human genome, with the thought that other regions paralogous to the MHC might be

best suited for initial work. Studies will be required to compare genes that are involved in the same pathways or networks, especially those that have evolved with high levels of polymorphism. Individual locus and haplotype variation in these paralogous regions characteristic of both specific ethnicities and specific diseases need to be studied to determine whether paralogous genes with similar or related functions might explain ethnic variation in the pathogenesis of certain diseases such as autoimmune diseases.

Keywords

Dermis
The dermis, or corium, is the thickest tissue layer of the skin and underlies the epidermis. It contains very large amounts of extracellular matrix components that provide strength (collagen fibers), elasticity (elastin fibers), and compressibility (proteoglycans) to the skin. The dermis is extensively vascularized and innervated.

Epidermis
The outermost layer of the skin consisting predominately of epidermal cells arranged in six histologically distinct layers: stratum corneum, stratum lucidum, stratum

granulosum, stratum spinosum, stratum basale, and basement membrane zone. The epidermis provides the major barrier to water loss and microbial invasion of the skin.

Wound Healing
The process of repairing injuries to skin that normally progresses through sequential phases of hemostasis, inflammation, repair, and remodeling.

The skin is the one organ of the body that is constantly exposed to a changing environment. Maintaining its integrity is a complex process, and assaults from surgical incisions, injuries, or burns can lead to life-threatening consequences without appropriate treatment.

Human skin is divided into two primary layers – epidermis (outermost layer) and dermis (innermost layer) (Fig. 1). These two layers are separated by a structure called the *basement membrane*. Beneath the dermis is a layer of loose connective tissue called the *hypodermis* or *subcutis*, and beneath the subcutis is the fat layer. Major functions of the skin are protection, immunity, thermoregulation, sensation, metabolism, and communication. The skin of the average adult covers approximately 3000 square inches, or an area almost equivalent to 2 m^2. From birth to maturity the skin covering will undergo a sevenfold expansion. It weighs about 6 lbs (or up to 15% of total adult body weight), is the largest organ, and receives one-third of the body's circulating blood volume. The skin forms a protective barrier from the external environment while maintaining a homeostatic internal environment. Epidermal appendages – nails, hair follicles, sweat or sebaceous glands – which are lined with epidermal cells, are also present in the skin. During the healing of partial-thickness wounds, these epidermal cells migrate to resurface the wound. This organ is capable of self-regeneration and can withstand limited mechanical and chemical assaults. The skin varies in thickness from 0.5 mm in the tympanic membrane to 6 mm in the soles of the feet and the palms of the hands. Variations are attributable to differences in the thickness of the skin layers covering underlying organs, bones, muscle, and cartilage. Diseases of the skin can result from genetic causes, so-called genodermatoses, infection, immune dysfunction, and trauma. Skin diseases can involve some or all of the layers of the skin.

1 Embryology of Skin

Skin is derived from both ectoderm and mesoderm (see Fig. 1). The epidermis, pilosebaceous glands, apocrine and eccrine sweat glands, hair follicles, and nail units are derived from the surface ectoderm. The ectodermal skin appendages develop with the formation of epidermis at 11 weeks of gestation and complete their development in 5 months. Melanocytes, nerves, and specialized sensory units originate from the neuroectoderm. As early as 5

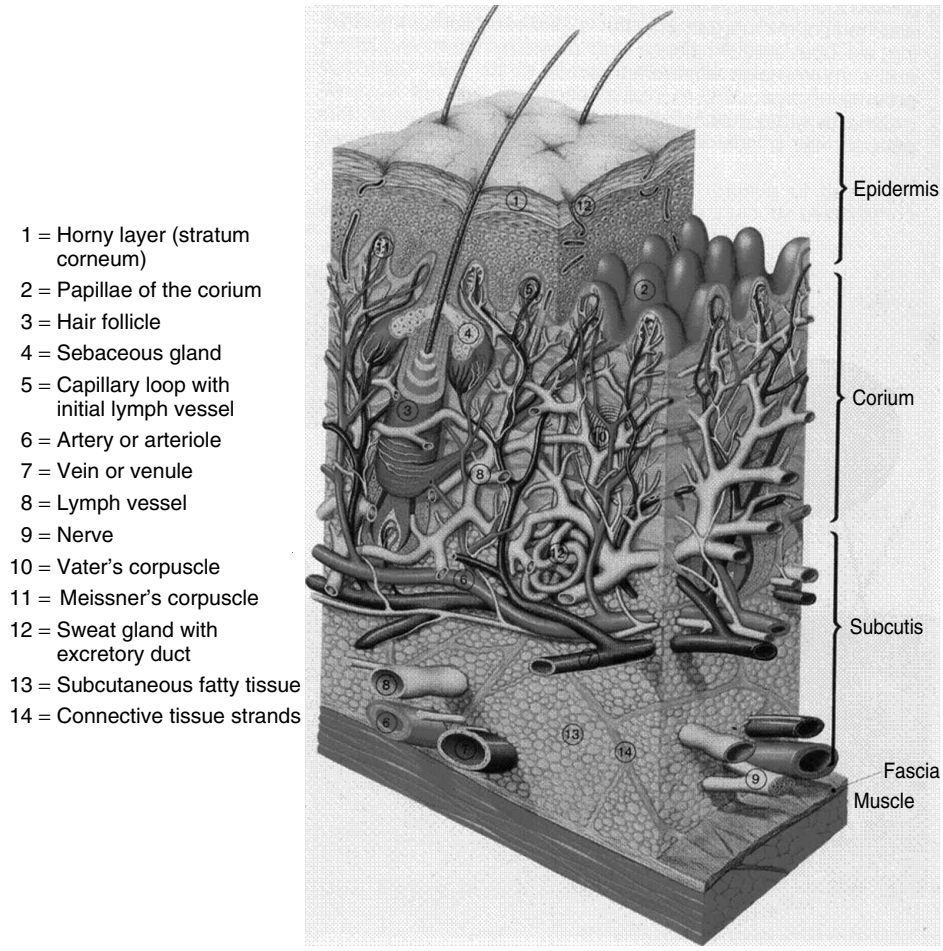

Fig. 1 Structure of skin. Major divisions of skin are the epidermis, dermis (corium), and subcutis (fat), which are separated from muscle by a layer of fascia.

weeks of human gestation, the neuroectodermal components from the neural crest cells can be detected.

The epidermis initially comes from a single layer of ectodermal cells. Soon they differentiate and form a second layer of squamous epithelium, called *periderm*, over the surface. Peridermal cells are eventually replaced by the cells arising from the basal layer.

The keratinized peridermal cells desquamate and form a part of the vernix caseosa, which covers fetal skin throughout pregnancy. It is the greasy white substance enveloping the baby at birth and functions to protect the fetal skin from uremic amniotic fluid and to act as a lubricant during birth. All components of epidermis are present at birth, and the peridermal cells are completely replaced by stratum corneum within a few months after birth. The mesoderm-derived skin elements form the structural components of dermis: the macrophages,

mast cells, Langerhan's cells, Merkel cells, fibroblasts, blood and lymphatic vessels, and fat cells. By 11 weeks of gestation the mesoderm-derived mesenchymal cells begin to produce collagen and elastin connective tissue fibers.

The dermis projects into the epidermal ridges and forms dermal papillae. The initial, simple, endothelium-lined capillaries in dermis acquire a muscular layer from the surrounding mesoderm-derived myofibroblasts, and as more simple single-layered vessels grow out from them, become arterioles and venules. The embryology of skin has profound implications for tumor genesis, prognosis, and treatment.

2 Epidermis

The epidermis, the outermost skin layer, is avascular and is derived from embryonic ectoderm. This layer is relatively uniform in thickness over the body and is between 75 and 150 μm, except for the soles and palms where thickness is between 0.4 and 0.6 mm. The epidermal layer is constantly being renewed with a turnover time ranging from 26 to 42 days. Complete epidermal renewal occurs between 45 and 75 days, or about every 2 months. The epidermal layer is composed of stratified squamous epithelial cells, or keratinocytes, and is divided into five layers. These layers, beginning from the outermost to the innermost, are the stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum basale (stratum germinativum, or simply, basal layer).

2.1 Stratum Corneum

The stratum corneum, or horny layer, is the top layer and is composed of dead keratinized cells. These squames, or corneocytes, are the cells that are abraded by the daily mechanical and chemical trauma of hand washing, scratching, bathing, exercising, and changing of clothes. The stratum corneum is composed of layers of thin, stacked, pancake-appearing, anucleate cells. These cells are filled with about 80% keratin, a tough, fibrous, insoluble protein; hence, they are called *keratinocytes*. Keratinocytes are initially formed in the basal layer and undergo the process of differentiation. The normal stratum corneum is composed of completely differentiated keratinocytes. Keratin is resistant to changes in temperature or pH and to chemical digestion by trypsin and pepsin. This same protein is found in hair and nails; in these structures, keratin is referred to as *hard* keratin compared with the *soft* keratin of the skin. Stratum corneum thickness varies with age, sex, and disease. The deeper layer of the stratum corneum is called the *stratum compactum* and the keratin in these cells is more densely packed. These cells also have a diminished capacity to bind water. Cells in the uppermost layer are partly shed because of the proteolytic degradation of the desmosomes and this layer is also called the *stratum dysjunctum*.

2.2 Stratum Lucidum

The stratum lucidum is the layer directly below the stratum corneum. This layer is found in areas where the epidermis is thicker, such as the palms of the hands or soles of the feet, and where it is prominent but absent from thinner skin, such as the eyelids. This layer can be one to five cells thick and is transparent. Cell boundaries are often difficult to identify in histological sections under a light microscope. The stratum lucidum is a

transitional layer where active lysosomal enzymes degrade the nucleus and cellular organelles before the cells move into the stratum corneum.

2.3 Stratum Granulosum

The stratum granulosum, or granular layer, is beneath the stratum lucidum when present; otherwise it lies beneath the stratum corneum. This layer is one to five cells thick and is so named because of the granules present in the keratinocytes of this layer. The cells of the stratum granulosum have not yet been compressed into a flattened layer and are diamond shaped. The structures contained in these cells are keratohyalin granules, which become intensely stained with the appropriate acid and basic dyes. The proteins contained in these granules, profilaggrin, intermediate keratin filaments, and loricrin, helps to organize the keratin filaments in the intracellular space. Cells in this layer still have active nuclei.

2.4 Stratum Spinosum

The stratum spinosum is the next layer below the stratum granulosum. This layer is often described as the prickly layer because cytoplasmic structures in these cells take on a spicule morphology. Generally, the cells of this layer are polyhedral in shape. A prominent feature of the prickle layer is desmosomes, a type of cell–cell junction. Cells in this layer begin to synthesize involucrin, a soluble precursor of the cornified envelopes. The spinous cells contain large bundles of newly synthesized keratin filaments, K1/K10 in addition to K5/K14 still present from the basal layer.

2.5 Stratum Basale, or Stratum Germinativum

The stratum basale, or stratum germinativum, is the innermost epidermal layer. It is often referred to simply as the *basal layer*. It is a single layer of mitotically active cells called *basal keratinocytes* or *basal cells*. These active cells respond to several factors, such as extracellular matrix (ECM), growth factors, hormones, and vitamins. Skin metabolism is mediated by glucose. Glucose utilization in the skin is comparable to muscle. Glucose leaving the circulation crosses the basement membrane and forms a concentration gradient that decreases as it moves to the upper layers of the epidermis.

Once cells leave the basal layer they begin an upward migration, which can take 2 to 3 weeks. It takes approximately 14 days for a cell to move to the stratum corneum and another 14 days to move through the stratum corneum and desquamate. After leaving the basal layer the cells begin the process of differentiation. All layers of the epidermis consist of peaks and valleys. This arrangement is more dramatic in the basal layer. In fact, the epidermal protrusions of the basal layer that point downward into the dermis are called *rete ridges* or *rete pegs*. Rete ridges are partly responsible for anchoring the epidermis, thus providing structural integrity. Basal cells in the base of the rete ridges have an increased proliferative capacity compared with cells at the top of the ridges.

Epidermal stem cells comprise about 10% of the basal cell population. These stem cells have a slow cell cycle and when their DNA is labeled with a radioactive nucleic acid, they retain the label for long periods. Hence, these stemlike cells are called *label retaining cells*. Once cell division occurs, the daughter cell that

will undergo differentiation as it moves toward the stratum corneum is called the *transient amplifying cell*. These transient amplifying cells make up about 50% of the basal keratinocyte population. A portion of the stem cell population is found in the epidermal crypts of the rete pegs and in the bulge region of hair follicles. Dividing cells go through the cell cycle and the G_1 phase is shortened in states such as wound healing. The normal keratinocyte cell cycle time is 300 h, but it may be as short as 36 h in psoriasis. These stem cell compartments and the transient amplifying cells are both capable of limited or continuing cell division, and thus, are the cells most likely to reside long enough in the skin to undergo genetic modifications leading to the development of skin cancers. The use of stem cells alone and in combination with tissue engineering approaches is an area of active research and development.

Also distributed in this layer are melanocytes, the cells responsible for skin pigmentation. These are dendritic cells arising from the neural crest that synthesize melanin. Melanocytes can be detected at 50 days gestation in fetal development. Under normal conditions melanocytes rarely divide. In normal skin, the number of melanocytes present is nearly the same regardless of skin color. There is approximately one melanocyte for every 36 basal cells. Dendritic melanocyte structures are responsible for the transfer of pigment to a large number of keratinocytes. The primary difference between light- and dark-skinned individuals is the size and distribution of the melanosomes, the structures containing the melanin pigment, and the activity of the melanocytes. Carotene or carotenoids are responsible for imparting the yellow hue to the skin of some individuals.

2.6 Basement Membrane Zone

The basement membrane zone (BMZ), or dermal–epidermal junction (DEJ), is the area that separates the epidermis from the dermis. The BMZ anchors the epidermis to the dermis and is the layer that is affected in blister formation. During wound healing the BMZ is disrupted and must be reformed. Closer examination of the BMZ in the past decade has revealed it to be more complex than previously believed. Basal keratinocytes use hemidesmosomes to structurally and functionally attach to the BMZ. The BMZ is subdivided into two distinct zones – lamina lucida and lamina densa. The lamina lucida is so named because it is an electron-translucent zone compared with the electron-dense zone of the lamina densa. The major proteins found in the BMZ are fibronectin, an adhesive glycoprotein; laminin, also a glycoprotein; type IV collagen, a nonfiber-forming collagen; and heparan sulfate proteoglycan, a glycosaminoglycan that probably acts as a type of ground substance. A lesser amount of type VII collagen is present, but it plays a very important role in attachment of cells to the lamina densa of the BMZ. Type VII collagen molecules form antiparallel dimers with the associated C termini linked by disulfide bonds. The N termini are linked into the basement membrane and anchoring plaque of epidermal cells in the stratum basale. Mutations of the type VII collagen gene that disrupt the proper association of the dimers leads to the dystrophic form of epidermolysis bullosa, a family of disorders characterized by separation of the epidermis from the dermis by relatively minor shear forces or trauma, resulting in blister-like injuries. This family of disorders, most of which are inherited, range in severity from mild to the severely

disabling and life-threatening diseases. In severe epidermolysis bullosa, blisters are not confined to the outer skin. They may develop inside the body, in such places as the linings of the mouth, esophagus, stomach, intestines, upper airway, bladder, corneal epithelial layer, and the genitals. This rare genetic disorder affects all ethnic and racial groups. Estimates indicate that as many as 100 000 Americans suffer from some form of epidermolysis bullosa, and depending on the severity, have significantly shortened life expectancy.

3 Dermis

The dermis, or corium, is the thickest tissue layer of the skin. Compared with the cellular epidermal layer, the dermis is sparsely populated primarily by fibroblast cells and is vascularized and innervated. The dermal layer is derived from the middle embryonic germ layer, the mesoderm. Dermal thickness ranges from 2 to 4 mm but on average is 2 mm. Variations in dermal thickness account for differences in total skin thickness that have been measured throughout the body. The dermis of the back is thicker than the dermis covering the scalp, forehead, abdomen, thigh, wrist, and palm.

3.1 Papillary Dermis

The papillary dermis lies immediately below the BMZ and forms interdigitating structures with the rete ridges of the epidermis called *dermal papillae*. The dermal papillae contain capillary loops, which supply the necessary oxygen and nutrients to the overlying epidermis via the BMZ. The collagen fibers contained in the papillary dermis are much smaller in diameter and form smaller, wavy, cable-like structures compared with the reticular dermis. This portion of the dermis also contains small elastic fibers and has a greater proportion of ground substance than the reticular dermis.

3.2 Reticular Dermis

The reticular dermis is the area below the papillary dermis and forms the base of the dermis. The collagen fibers in this layer are thicker in diameter and form larger cable-like structures. There is no clear separation of papillary and reticular dermis because the collagen fibers change in size gradually between the two layers. Thicker elastic fibers are found in the reticular dermis but substantially less ground substance is present. A complex of cutaneous blood vessels is also found in this part of the dermis.

3.3 Dermal Vasculature

The dermal vasculature consists of a network of papillary loops, supported by a deep horizontal plexus. The vasculature functions to provide nutritional support, immune surveillance, wound healing, thermal regulation, hemostasis, and inflammation. The complete formation of the vascular system involves both vasculogenesis and angiogenesis. Vasculogenesis is the process that occurs *de novo* during embryonic development, and this process is mediated by angioblasts that are derived from embryonic mesodermal cells. Angiogenesis is the process whereby new vessels are formed from the vascular endothelial cells of preexisting vessels. Angiogenesis is the process involved in wound

healing, tumor growth and metastasis, hemangiomas, telangectasia, psoriasis, and scleroderma. Until recently, angiogenesis during wound healing was thought to only involve proliferation of vascular endothelial cells from capillaries around the wound, but recent data indicate that some of the cells that form new capillaries in wounds are actually angioblasts that originate in bone marrow, circulate to the wound and become incorporated into the new capillaries. Vascular endothelial growth factor (VEGF), also known as *vascular permeability factor* (VPF) is secreted by keratinocytes in response to hypoxia and is a major factor responsible for the stimulation of angiogenesis. VEGF/VPF is known to increase during wound healing. Other factors known to stimulate angiogenesis include acidic and basic fibroblast growth factor (FGF), interleukin-8, platelet-derived endothelial growth factor, placental growth factor, transforming growth factor α and β, oncostatin M, angiogenin, and heparin binding epidermal growth factor. Inhibitors of angiogenesis include angiostatin, thrombospondin, endostatin, interferon-γ, interleukin-12, and platelet factor 4.

3.4 Extracellular Matrix Proteins

3.4.1 Collagen

Collagen is the major structural protein found in the dermis and is secreted by dermal fibroblasts as tropocollagen (Fig. 2). After additional extracellular processing, mature collagen fibers are formed. Normal human dermis is primarily composed of type I collagen, a fiber-forming collagen. Type I collagen represents about

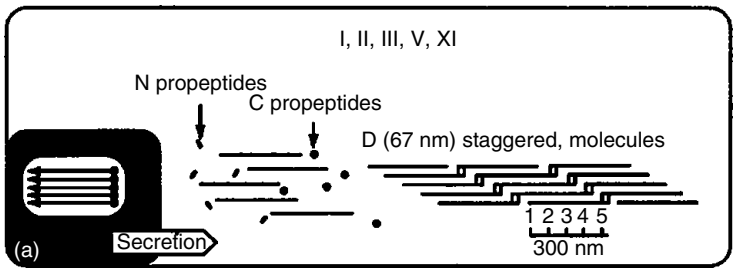

Fig. 2 Different types of collagen molecules. All collagen molecules contain some segments of triple stranded helix. (a) The fibrillar collagen molecules (types I, II, III, V, and XI) assemble in a head-to-tail and staggered, side-by-side alignment and are the most abundant types of collagens. They provide high tensile strength to the extracellular matrix. (b) The network-forming collagen molecules (types IV, VIII, and X) assemble in head-to-head and head-to-tail alignments, which generates a sheetlike structure with ''pores'' in basement membranes. (c) The fibril-associated collagen molecules with interrupted triple helices (FACITs) bind with collagen fibrils, but also bend at the interrupted helix hinge region, and associate with other molecules in the surrounding extracellular matrix. (d) Type VI collagen molecules retain globular regions at the N and C termini which form ''beads on a chain'' like appearance when they associate into tetramers. (e) Type VII collagen molecules also retain globular regions at the N and C termini, associate in tail-to-tail configuration, while the N terminus associates with basement membrane and anchoring plaque regions of epidermal cells.

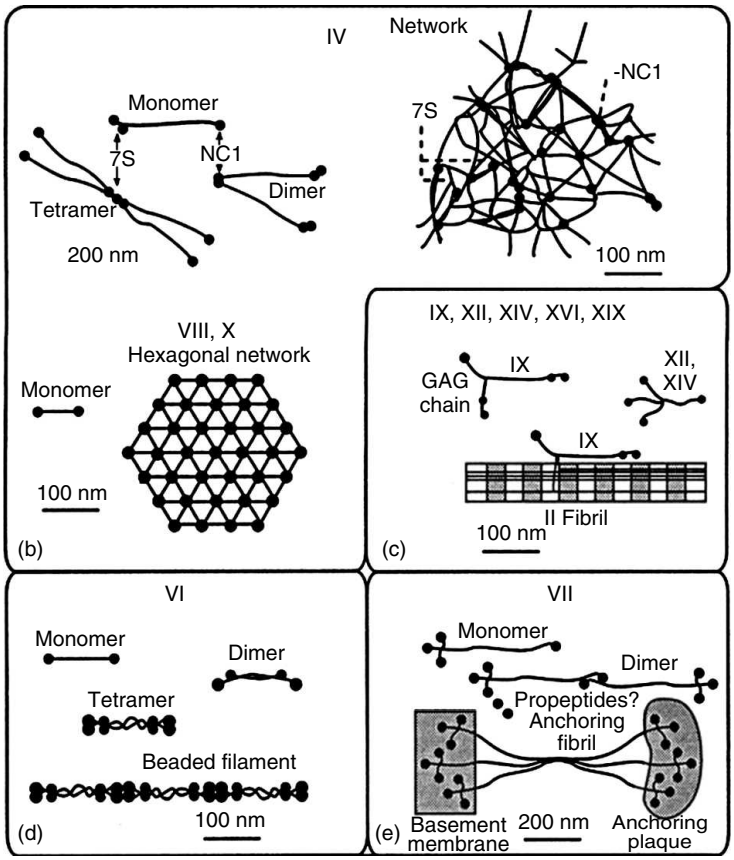

Fig. 2 (*Continued*)

77 to 85% of the collagen present, and type III collagen, also a fiber-forming collagen, represents the remaining 15 to 23%. Types V and VI collagen are also found in small amounts. Associated with the major fiber-forming collagens are types IX and XII collagens. These fibril-associated collagens do not self-associate into large self-polymers, but instead monomers bind to the sides of collagen fibers and extend a segment away from the fiber into the surrounding matrix that binds to proteoglycans (PGs). Thus, these fibril-associated collagen molecules help to bind collagen fibers with the other components of the ECM. Collagen is the protein that gives the skin its tensile strength. Chemically processed collagen from bovine sources results in leather handbags valued for their strength and long life. The primary amino acids that constitute collagen are proline, glycine, hydroxyproline, and hydroxylysine.

3.4.2 Elastin

Elastin, another protein found in the dermis, provides the skin with its elastic recoil. This prevents the skin from being permanently reshaped. Elastin is a fiber-forming

protein like collagen and has a high amount of proline and glycine. However, unlike collagen, elastin lacks large amounts of hydroxyproline. Elastin fibers form structures similar to a spring or coil that allow this protein to be stretched and, when released, to return to its inherent configuration. It accounts for less than 2% of the skin's dry weight. Other cells found in the dermis are mast cells, macrophages, and lymphocytes. All of these cells are involved with immune surveillance of the skin, often referred to as the *skin immune system* (SIS).

3.4.3 Proteoglycans and Glycosaminoglycans

The major proteins found in the dermis are collagen and elastin. The other category of proteins found occupying the space between collagen and elastin fibers is referred to as the *ground substance*. This category of proteins is largely composed of proteoglycans and glycosaminoglycans (GAGs). Included in this category of proteins are chondroitin sulfates and dermatan sulfate (versican, decorin, biglycan), heparan and heparan sulfate proteoglycans (syndecan, perlecan), and chondroitin-6 sulfate proteoglycans. Although these proteins only account for about 0.2% of the dry weight of the dermis, these large molecules are capable of binding up to 1000 times their volume. Thus, PGs and GAGs play a role in regulating the water-binding capacity of the dermis that can determine dermal volume and compressibility. Hyaluronan is also found in the dermis and its higher abundance in fetal skin where it forms a watery less stable matrix allows greater cell movement and is a factor in scarless healing. This material can bind growth factors and provide cellular linkages with other matrix materials. Fibroblasts are the cells distributed in this layer that synthesize and secrete these proteins. The dermis is a matrix supporting the epidermis and can be divided into two areas – papillary dermis and reticular dermis.

3.5 Hypodermis

Hypodermis, or superficial fascia, forms a subcutaneous layer below the dermis. This is an adipose layer containing a subdermal plexus of blood vessels giving rise to the cutaneous plexus in the dermis, which in turn gives rise to the papillary plexus and loops of the papillary dermis. The hypodermis attaches the dermis to underlying structures. This layer provides insulation for the body, a ready reserve of energy, and additional cushioning, and it also adds to the mobility of the skin over underlying structures. In certain pathologic disease states such as Werner's syndrome and scleroderma, this layer is largely absent.

4 Skin Functions

The skin provides protection against aqueous, chemical, and mechanical assaults; bacterial and viral pathogens; and ultraviolet radiation (UVR). It also prevents excessive loss of fluids and electrolytes to maintain the homeostatic environment. The effectiveness of the skin in preventing excessive fluid loss can be seen in burn patients; patients with burns involving 30% of their body can lose up to 4.1 L of fluid compared with 710 mL for a normal adult. The skin maintains the internal milieu and a progressive decrease in water content across the epidermal layers helps prevent excessive transepidermal water loss under basal conditions. The basal layer is

about 65 to 70% water decreasing to 40% in the granular layer and progresses to the stratum corneum that is 15% water. Skin barrier function is so effective that percutaneous drug delivery is limited and in general compounds are restricted to those with a molecular mass of 500 Da or less with a daily dose around 10 mg or less. Protection against mechanical assaults is mainly provided by the tough fibroelastic tissue of the dermis, collagen, and elastin. Collagen, the most abundant protein in mammals, represents 25% of total weight and provides tensile strength, which makes the skin resistant to tearing forces. Elastin is distributed with collagen but in smaller amounts. Large concentrations of elastin are present in blood vessels, especially the aortic arch near the heart.

4.1 Protection Against Pathogens

Protection against aqueous, chemical, bacterial, and viral pathogens is provided by the stratum corneum, secretions from the sebaceous glands, and the SIS. The primary line of defense against all of these agents is an intact stratum corneum. As mentioned previously, the insoluble protein keratin found in the horny layer provides good resistance. In addition, the constant shedding of squames from the stratum corneum prevents the entrenchment of microorganisms.

Sebum, a lipid-rich oily substance secreted by the sebaceous glands onto the skin surface, usually via hair follicles and shafts, provides an acidic coating with a pH ranging from 4 to 6.8 and a mean pH of 5.5. This acidity and natural antibacterial substances found in sebum retard the growth of microorganisms. These glands are stimulated by sex hormones (androgens) and become very active during adolescence. Sebum, along with keratin, provides resistance to aqueous and chemical solutions. When sebaceous glands occur in association with hair follicles, they are called a *pilosebaceous unit*. Sebaceous glands are not found on palms or soles and occur in areas that lack hair, such as the lips. These glands are largest on the face and when associated with hair follicles. Sebaceous glands may increase in size by 100 to 150 times as the sebum accumulates. Maximum secretion occurs in the late teens to early twenties. Rates of secretion are higher in men and decline 32% per decade in females compared to 23% per decade in males.

Resistance to pathogenic microorganisms is also provided by normal skin flora through bacterial interference. Conceptually, there are two categories of skin flora – resident (the bacteria normally found on a person) and transient (bacteria that are not normally found on a person and are usually shed by daily hygienic practices, such as bathing and hand washing). Resident bacteria are found on exposed skin; moist areas such as the axilla, perineum, and toe webs; and covered skin. Bacterial microcolonies are found in hair follicles and at the edges of squames as halos in the upper loose surface layers. The following species of bacteria are found in human skin: Staphylococcus, Micrococcus, Peptococcus, Corynebacterium, Brevibacterium, Proprionibacterium, Streptococcus, Neisseria, and Acinetobacter. The yeast Pityrosporum and the mite Demodex are also found. Not all species are found on any one individual, but most carry at least five of these genera. Normal viral floras are not known to exist. However, viruses have been detected in compromised skin and in individuals who are not immunocompetent.

There is an association between skin pH and bacteria, for example, *Propionibacterium acnes* grows well at pH values such as 6.0 and 6.5, but there is a marked decrease in growth at pH 5.5. However, it appears that this relationship can vary depending on pH and the specific bacterial species involved and body location. More recently the formation of bacterial biofilms is being scrutinized, and the role of normal skin flora on the formation of these biofilms is an area of active investigation. Biofilms are essentially an extracellular polysaccharide matrix or glycocalyx in which microorganisms are embedded. These biofilms are made up of mixed bacterial species living in their own microniche in a complex, metabolically cooperative microbial community that maintains its own form of homeostasis and rudimentary circulatory system. Biofilms are resistant to host immune responses and are markedly more resistant to antibiotic and topical bactericidal agents. Reports indicate that biofilm cells can be at least 500 times more resistant to antibacterial agents. The formation of these biofilms are familiar to clinicians where they can be found on endotracheal tubes, Hickman catheters, central venous catheters, contact lenses, and orthopedic devices. *Pseudomonas aeruginosa* is known to form biofilms in conjunction with other bacterial species. Quorum sensing is a feature of the bacteria in biofilm formation. These biofilms complicate the eradication of infections because they give rise to sessile and planktonic bacteria. Planktonic bacteria can be cleared by phagocytosis, antibodies, and antibiotics. The sessile bacteria in biofilms can evade antibiotics by giving rise to planktonic bacteria that responds to antibiotics and the host immune responses while the sessile bacteria remain. Many times cycles of antibiotic treatment are instituted to no avail because the symptoms of infection recur. In these situations, biofilm formation should be suspected and the surgical removal of the sessile population will most likely be required to eliminate the pathogenic bacteria. Moist skin areas such as the axilla, perineum, toe webs, hair follicles, nail beds, and sweat glands, are especially prone to an increased presence of bacteria. Protection from bacterial invasion is in part mediated by proteins called *defensins*. Findings show that β-defensin is abundant in skin and may be important for wound healing. Defensins act in conjunction with phagocytosing neutrophils and the membrane attack complex of complement. Thus, optimal skin and wound care is a cornerstone of clinical practice to prevent the progression from bacterial colonization to infection.

4.2 Protection Against Ultraviolet Radiation

Protection against UVR is provided by skin pigmentation, which results from synthesis of the pigment melanin. Harmful effects are primarily attributable to the longwave form of UVR, or UVA, which ranges spectrally from 320 to 400 nm and UVB or shortwave ultraviolet ranging from 290 to 320 nm. The shorter the waves, the more dangerous they become. UVC is effectively blocked by an intact ozone layer. With holes appearing in the ozone layer there is concern over the effects that this may have on skin diseases caused by UVR. Because of the increased synthesis, amount, and distribution of melanin in dark skin, these individuals are better protected against skin cancer. Melanin is distributed in all layers of the epidermis in dark skin in contrast to light skin. Exposure to UVR can lead to skin cancer, sunburn (first- or second-degree burns),

compromised immunity, and long-term skin damage. Sun exposed epidermal skin is thicker and rougher than unexposed skin. It is more prone to benign and malignant growths and to have a greater decrease in Langerhans cells. Sun exposed dermis has increased elastic properties probably due to increased synthesis of matrix metalloproteinases (MMPs), which cause an increase in fragmented collagen fibrils compared to unexposed dermis.

4.3 Skin Immune System

The SIS also provides protection against invading microorganisms and antigens. The cells of the skin that provide immune protection are the Langerhans' cells, an antigen-presenting cell found in the epidermis; tissue macrophages, which ingest and digest bacteria and other substances; mast cells, which contain histamine (released in inflammatory reactions), and dendrocytes. Both macrophages and mast cells are found in the dermis. Langerhans cells are responsible for the recognition, uptake, processing and presentation of soluble antigens, and haptens to sensitized T lymphocytes. This occurs through the binding of T cells to Langerhans cells. Exposure to UVB light decreases the functional capability of the Langerhans cells.

Tissue macrophages are derived from monocytes, which are derived from bone marrow precursor cells. Macrophages are among the most important cells of the SIS because they are versatile. Once these monocytes migrate into the tissue they differentiate and become macrophages. Cells in the dermis that are not completely differentiated are difficult to distinguish, and much effort has been made to recognize the various cells in the dermis in the last decade. Macrophages, in addition to their antibacterial activity, can process and present antigen to immunocompetent lymphoid cells; are tumoricidal; and can secrete growth factors, cytokines, and other immunomodulatory molecules. Macrophages are involved in coagulation, atherogenesis, wound healing, and tissue remodeling.

Mast cells are usually found distributed in the papillary dermis; around epidermal appendages, blood vessels, and nerves found in the subpapillary plexus; and in subcutaneous fat. These cells are distributed in connective tissue throughout the body in places where there is an interface of an organ with the environment. Mast cells contain or secrete on demand a host of proteins. Thus, mast cells are the primary effector cells in an allergic reaction. They are also involved in the presence of subacute and chronic inflammatory disease. Increased numbers of mast cells have been detected in chronic eczema, psoriasis, scleroderma, porphyria cutanea tarda, lichen simplex chronicus, lichen planus, and healing wounds. As a part of the SIS, mast cells play a role in protection against parasites; stimulate chemotaxis; promote phagocytosis; are involved in the activation and proliferation of eosinophils; are capable of altering vasotension and vascular permeability; and can promote connective tissue repair and angiogenesis. Their role in tumor surveillance awaits further study.

Dermal dendrocytes are highly phagocytic cells found in the papillary and upper reticular dermis. They are also distributed near vessels in the subpapillary plexus, reticular dermis, and subcutaneous fat. These are immunologically competent cells that are highly phagocytic and can be recognized as melanophages. In fetal, infant, photoaged, and pathological skin conditions, such as psoriasis or eczema

their number is increased. In malignant fibrotic tumors and fibroproliferative lesions such as keloids, scars, and scleroderma, their numbers are decreased.

4.4 Thermoregulation

Thermoregulation of the body is provided by the skin, which acts as a barrier between the outside and inside environments to maintain body temperature. The two primary thermoregulatory mechanisms are circulation and sweating. Blood vessels can either dilate to dissipate heat or constrict to shunt heat to underlying body organs. When dilated, these vessels have an increased blood flow and release heat by conduction, convection, radiation, and evaporation. Vasoconstriction is often accompanied by actions of the arrector pili muscle attached to hair follicles, which results in the hair standing vertically. In mammals that depend on hair for warmth, this action fluffs up the fur to increase thermal capacity. The bulge around the hair shaft that is visible when this occurs is commonly referred to as goose bumps. In humans, shivering is more important for maintaining body temperature when the outside environment is cold than the vertical orientation of hair. In cold weather, the ''core'' body temperature encompasses a smaller zone, whereas in warm weather the ''core'' is expanded. Sensations of cold and warm are generally detected below 30 °C and above 37 °C. Clinically it has been estimated that for each 1 °C (1.8 °F) increase in fever there is a 13% increase in a patient's fluid and calorie needs. At rest, the trunk, viscera, and brain account for 70% of heat production but are only 36% of body mass. However, during exercise, muscle and skin account for 90% of heat production while representing 56% of body mass.

Hair follicles, unlike other skin structures have a repeated cycle of growth and regression. Follicle development begins in the fourth month of gestation. The hair growth cycle consists of anagen (growth phase), catagen (follicle involution), and telogen phases (dormant or resting phase). A population of epidermal stem cells is found in the bulge region of the hair follicle, and this cell population contributes to epithelialization of partial-thickness wounds. Hair shape varies depending on ethnicity and location. Asians have the largest diameter scalp hair and Caucasians the smallest. In the scalp, about 85% of hair is in anagen phase and 15% in telogen phase with the anagen phase lasting from 2 to 5 years. On the extremities, anagen lasts from 22 to 28 days.

Sweating occurs when there is an increase in the activity of the sweat glands. It has been estimated that there are about two to five million sweat glands. Sweat glands are of two types – eccrine and apocrine. Eccrine glands arise from epidermal invagination and are found abundantly on the palms of the hand and soles of the feet. There are anywhere from 2 to 5 million glands, 0.05 to 0.1 mm in size. These glands are largely under the control of the nervous system, responding to temperature differences and emotional stimulation. Muscular activity also influences their secretory activity. The sweat glands, located in the dermis as a coil, secrete fluid that is 99.0 to 99.5% water with the remainder consisting of sodium chloride, urea, sulfates, and phosphates. The pH is slightly acidic. Thermoregulatory control occurs as a result of cooling when fluid is evaporated from the skin surface, since such evaporation requires heat. The odor associated with sweat is

largely a result of bacterial action. Eccrine sweat glands are capable of producing 1 to 4 L h^{-1} resulting in a 75 to 90% reduction in body heat. Man is capable of losing heat more rapidly and for longer periods than any other animal.

Apocrine sweat glands are usually found in association with hair follicles but do not play a significant role in thermoregulation. These coiled tubular glands are present in the axilla and anogenital area; modifications of these glands are found in the ear and it secretes ear wax, or cerumen. There are approximately 100 000 apocrine glands each 2 to 3 mm in diameter. Secretions from these glands are small in amount, turbid, and contain iron, carbohydrates, and lipids.

4.5 Sensation

Nerve receptors located in the skin are sensitive to pain, touch, temperature, and pressure. Nerve fibers are located in the dermis and throughout the epidermis. Nerve structures found in the skin originate from the neural crest and are detectable in the developing embryo around 5 weeks. When stimulated, these receptors transmit impulses to the cerebral cortex where they are interpreted. Combinations of these four basic types of sensations result in burning, tickling, and itching. These sensations are propagated by unmyelinated free nerve endings, Merkel's cells, Meissner's corpuscles, Krause's end bulbs, Ruffini's terminals, and Pacini's corpuscles. Identification of particular responses with specific nerve structures has not been successful. In part, the reason is that some receptors seem to respond to a variety of stimuli. However, it is known that Meissner's corpuscles are involved in touch reception; Pacini's corpuscles respond to pressure, coarse touch, vibration, and tension; and free nerve endings respond to touch, pain, and temperature. Skin sensation is a part of the body's integrative response to protect itself from the surrounding environment. Sensation assists with the skins regulatory function and can signal sweating, shivering, weight shifts, laughter, and scratching.

Merkel cells function as mechanoreceptors and in the epidermis these cells produce nerve growth factor, whereas in the dermis, Merkel cells express receptors for nerve growth factor. Merkel cells are found around the arrector pili muscle in the bulge region of hair follicles and contribute to the development of eccrine sweat glands, nails, and nerves of the skin.

Sensation also moderates psychobiologic phenomena made famous by Harlow, who demonstrated the preference of young animals for warm objects and those that provided better tactile sensitivity. In addition, early studies by Spitz in 1947 pointed to the importance of touch in mediating social interactions with children and infants. Deprivation of touch can lead to psychomotor retardation and an increased risk of death. Other studies on touch indicate that it may be a factor in the development of atherosclerotic lesions in animals. Studies examining the effect of stroking, handling, talking, and playing with rabbits reported a 60% reduction in aortic atherosclerotic lesions in treated animals compared with controls, even though both groups were fed the same cholesterol-containing diet and had similar blood pressures, heart rates, and serum cholesterol levels.

In healing wounds, sensory nerves sprout abundantly for about the first three weeks subsequently returning to their normal density. The role of neuropeptides to stimulate the growth of connective tissue

is increasingly being recognized. This includes a role for these neuropeptides in modulating matrix production by fibroblasts and in acting as growth factors for keratinocytes.

4.6 Vitamin Metabolism

Synthesis of vitamin D occurs in the skin in the presence of sunlight. UVR converts a sterol (7-dehydrocholesterol) to cholecalciferol (vitamin D). Vitamin D participates in calcium and phosphate metabolism and is important in the mineralization of bone. Because vitamin D is synthesized in the skin but then transmitted to other parts of the body, it is considered an active hormone when converted to calcitriol (1,25-dihydroxycholecalciferol).

4.7 Social Communication

In addition to its biologic, structural, functional, and physiologic functions, human skin also functions as an organ of communication and identification. The skin over the face is especially important for identification of a person and plays a role in internal and external assessments of beauty. Injury to the skin can result in not only functional and physiologic consequences but also changes in body image. Scarring from trauma, surgery, or incisions can lead to changes in clothing choices, avoidance of public exposure, and a decrease in self-esteem. Research indicates that with increased scarring from facial acne, the self-image is progressively reduced. Adolescents are especially sensitive to physical appearance. As an organ of communication, facial skin along with underlying muscles is capable of expressions such as smiling, frowning, and pouting. The sensation of touching can also convey feelings of comfort, concern, friendship, and love.

5 Factors Altering Skin Characteristics

5.1 Age

Age is an important factor in altering skin characteristics. More recently the scarless healing of fetal tissue has come under more intense investigation. It has been found that wounds heal without scarring in fetal lambs up until 120 days of gestation. Collagen deposition in fetal wounds occurs more rapidly and in a normal dermal pattern. The ratio of type I and type III collagen is different in fetal skin, and about 30 to 60% of the collagen is type III while in adult skin it is about 10 to 15%. In addition, an important difference between fetal and adult skin is the amount of hyaluronic acid, a glycosaminoglycan. In the laboratory setting, topical application of hyaluronic acid has been associated with a reduction in scar formation in postnatal wounds. This glycosaminoglycan is associated with collagen, and it has been proposed that a hyaluronic acid–collagen–protein complex plays a role in fetal scarless healing. Transforming growth factor β-1 (TGF-β1) is the other modulator of scarless healing in fetal wounds. Fetal wounds usually contain less TGF-β1 compared with adult wounds. In addition, differential patterns of expression of the various isoforms of TGF-β also affect the relative amount of scarring in fetal versus adult wounds. Wounding in fetal skin also reveals differences in the cell responses with a decrease in inflammatory cells, particularly polymorphonuclear leukocytes and macrophages. Platelets do not aggregate in response to collagen or release the amount

of TGF-β and PDGF-AB like that in adult cells. Fibroblasts are able to migrate at a faster rate and synthesize more total collagen. Other differences in protease and inhibitor activity, level of growth factors, and expression of homeobox genes has been detected.

5.1.1 Neonatal Skin

At birth the skin and nails are thinner than those in an adult but will gradually increase in thickness with aging. Formation of the epidermal and dermal layers occurs within the first 2 weeks of embryonic development. Epidermal development is complete by the end of the second trimester, and at birth epidermal thickness is almost that of adult skin, although newborn skin is not as effective as adult skin in providing an effective barrier to transcutaneous water loss. On the other hand, development of the dermis lags behind and does not take on the characteristics of adult dermis until after birth.

The ratio of type I to III collagen is similar to the fetal ratios. Soluble collagen is about 24%, compared with 1% in the adult. This persists until about 6 months of age. The newborn dermis is about 60% as thick as that found in an adult, and as expected, the dermal fibers are significantly finer. Newborn dermis contains a much higher cellular component compared with mature adult skin. The epidermal–dermal junction remains flat until the beginning of the third trimester, and at birth, the rete ridges are only weakly developed, thus making premature and newborn skin subject to tearing or blistering. At birth the capillary beds do not have a mature adult pattern and are still disorganized. An adult pattern of capillary loops occurs at about 14 to 17 weeks after skin growth slows.

Immature skin, or skin from premature infants between 23 and 24 weeks of gestation up to 32 weeks of gestation, requires special attention compared with that of infants beyond 32 weeks. In particular, before 28 weeks gestation the skin is thin and poorly keratinized and functions weakly as a barrier. The skin of infants born at the limits of viability has been characterized as more suitable to an ''aquatic environment'' than to atmospheric conditions. Transepidermal water loss is high, and application of tape strips the outer immature epidermal layer that can leave behind raw damaged skin prone to infection and occasional scarring. At 24 weeks' gestation, transepidermal water loss can be 10 times greater per unit area compared with an infant born at term. Infants born between 22 and 25 weeks may require up to 4 weeks to develop a functional stratum corneum. In addition, premature infants have high evaporative heat losses resulting in increased risk for hypothermia.

Because premature infants have a greater surface-area-to-volume ratio compared with full-term infants, they are at an increased risk for skin complications and systemic toxicity from topically applied agents. These infants may also have alterations in metabolism, excretion, distribution, and protein binding of chemical agents, placing them at increased risk for local or systemic toxicity from soaps, lotions, or other topical agents. Other dangers are percutaneous absorption of topical agents, including antiseptics. Hemorrhagic necrosis of the dermis from alcohol absorption has been reported if the alcohol does not quickly evaporate and is sometimes mistaken for bruising. The use of topical antibiotic sprays containing neomycin should be avoided since it is an ototoxic aminoglycoside.

Thus, water-based topical antiseptics are preferred but should be used sparingly. Cleaning should be done with care using normal saline or water. Chlorhexidine, a commonly used antiseptic, is not known to have any adverse effects, but it is probably absorbed from the skin and should be used judiciously. Likewise, iodine has been reported to be absorbed, leading to goiter and hypothyroidism. If required, moisturizing creams or ointments may be applied to dry, flaking, or fissured skin, and the best agents appear to be those with little or no preservatives, since these offer the greatest benefit with decreased risk.

5.1.2 Adolescent Skin

The next period of change occurs in adolescence when hormonal stimulation results in increased activity of sebaceous glands and hair follicles. Sebaceous glands increase their secretory rate, and hair follicles, giving rise to secondary sexual characteristics, become activated. From adolescence to adulthood there is a gradual change in skin characteristics. By the time the skin reaches mature adulthood, several changes become apparent. The dermis decreases in thickness by about 20%, whereas the epidermis remains relatively unchanged. Epidermal turnover time is increased; this means that wound healing may take longer. For instance, in young adults, epidermal turnover takes about 21 days, but by 35 years of age this turnover time is doubled. Barrier function is reduced, and such reduction may increase the risk of irritation. The number of active melanocytes per unit body surface area decreases with aging, which means that protection against UVR is diminished. Skin dryness is also associated with aging and an increase in wrinkles. Sensory receptors are diminished in capacity, meaning that the skin is more likely to be burned or traumatized without perception. Vitamin D production is decreased and may be a factor in osteomalacia.

5.1.3 Elderly Skin

With aging there is a decrease in the number of Langerhans' cells, which affects the immunocompetence of the skin and can lead to an increased risk of skin cancer and infection by invading microorganisms. The density of Langerhans' cells changes from 10.0 per 3 mm cross section of unexposed skin in 22–26-year-old individuals to 5.8 per 3 mm cross section in 62–68-year-old individuals. There is also a decrease in mast cells and melanocytes. The inflammatory response is also decreased, which may alter allergic reactions and healing. The thermoregulatory capacity of the skin is also compromised by decreased number of sweat glands, diminished vascularity, and reduced subcutaneous fat. Epidermal–dermal junction changes, such as the flattening of the prominent dermal papillae and of the rete ridges, alter junctional integrity. Consequently, the skin is more easily torn in response to mechanical trauma, especially shearing forces. Because the epidermal rete pegs flatten, the unique microenvironment of the basal keratinocytes changes; it is thought that this explains the decrease in epidermal proliferative capacity with aging.

Skin elasticity decreases with age and is related to a combination of aging and solar damage. Microscopic analysis of collagen and elastin fibers reveals that these are more compact with a loss of ground substance from the spaces between these cable-like structures. Collagen fibers appear to be unwinding, while elastin fibers appear to be undergoing digestion. The degradation of elastin can be detected at about 30 years of age but becomes

marked at 70 years of age. Changes in dermal proteoglycans usually occur after 40 years of age. By 70 years of age, most of the elastin network is affected. Changes in collagen content and structure are mediated by an underexpression of procollagen, overexpression of collagenase (MMP-1), stromelysin (MMP-3) and gelatinase A (MMP-2), and decreased expression of tissue inhibitors of matrix metalloproteinase-1 (TMP-1). There is also a marked reduction in vascular beds in the vertical capillary loops in the dermal papillae. There is an approximate 35% decrease in the cross-sectional area of these loops in aged skin. It is thought that this leads to atrophy of the hair bulbs, sweat glands, and sebaceous glands. Because the hypodermis also becomes thinner, mature individuals are more prone to pressure necrosis. With aging there is a progressive loss of mechanoreceptors to one-third of their average density that occurs from the second to ninth decade.

Clinical observations established that repair of injuries to skin of aged persons (over 50 years old) proceeded much more slowly than injuries in skin of young persons, but with improved quality of scarring both microscopically and macroscopically. However, the molecular changes that caused these effects were not known until a series of experiments by Ashcroft and colleagues revealed that the slower healing and reduced scarring in postmenopausal women were associated with reduced levels of TGF-β1 protein and mRNA in wounds. Furthermore, treatment of postmenopausal women (or aged men) either with oral or topical estrogen, accelerated healing of skin wounds and elevated levels of TGF-β1 while simultaneously reducing levels of MMPs and elevating levels of the tissue inhibitors of metalloproteinases (TIMPs). Estrogen treatment also reduced inflammation in test wounds and reduced levels of neutrophil elastase, which was associated with increased levels of collagen and fibronectin in wound biopsies, resulting in the enhanced strength of wounds 80 days after injury. These data demonstrated that delays in wound healing in the elderly could be significantly diminished by topical estrogen in both male and female subjects.

Changes in hair color and hair follicles also accompany aging. Age-related changes in active melanocytes result in gray hair. About 50% of the body's hair will be gray by the age of 50 in about 50% of the population. This change is accompanied by a reduction in the number of hair follicles and a decrease in the diameter of the hair. The rate of hair growth is also decreased. Nail growth rates also decrease by 40 to 50%.

The density of skin melanocytes is relatively constant until about 40 years of age. By about 45 years of age, skin melanocytes have decreased in density to approximately half of that seen between 30 and 39 years of age. Melanocytes decrease 6 to 8% each decade after age 30. It is thought that loss of skin melanocytes contributes to an increase in the formation of skin cancers. Other overt changes are wrinkling and sagging, which occur as a result of loss of underlying tissue in addition to changes seen in collagen and elastin.

Changes in thermoregulatory capacity occur with age, and older individuals are more prone to hypothermia and heat stroke. This has been attributed to changes in blood capillaries and eccrine sweat glands. In healthy older individuals, sweating may be decreased by up to 70%. Sebum secretion also declines with age. Barrier function decreases with aging owing to the decreased level of all the

major lipid species, especially ceramides. In addition, corneocytes are larger and less cohesive. In addition to these changes, pain perception is dulled, and there is reduced skin reactivity upon exposure to irritants. Cutaneous immune function also changes with aging as seen by a reduction in Langerhans' cell density. Skin damaged by sun exposure, or actinically damaged skin, has been found to have a 50% reduction of Langerhans' cell density compared with sun-protected skin. Reduction in immunocompetence of the skin is thought to contribute in part to skin cancer in the elderly.

Other factors that may contribute to the development of skin cancer in aged individuals are cumulative exposure to carcinogens, diminished DNA repair capacity, decreased melanocyte density, and alterations in dermal matrix. Not surprisingly, wound healing in older individuals is delayed compared with that of younger individuals.

5.2 Sun

Excessive exposure to UVR can have harmful effects that accelerate aging of the skin. For this reason, the condition associated with UVR-damaged skin is referred to as photoaging. Dermatologically, it is called *dermatoheliosis*. Obvious clinical signs of photodamaged skin are dryness, tough leathery texture, wrinkling (as a result of collagen and elastin degeneration), and irregular pigmentation (from changes in melanin distribution). Excessive exposure to UV radiation increases the risk of developing skin cancers, such as basal or squamous cell carcinoma and malignant melanoma. Damage to the DNA of skin cells leads to transformation of cells and cancer. Changes also occur in epidermal and dermal cells; epidermal cells become thickened, fibroblasts become more numerous, and dermal vessels become dilated and tortuous. Langerhans' cells are reduced in number by about 50%, thereby diminishing the immunocompetence of the skin. Immediate short-term exposure to UVR can lead to sunburn. This type of red sunburn is the result of a vasodilatory response that increases blood volume. Whether an individual will become sunburned depends on the extent of skin pigmentation. Naturally, those with the least pigmentation are more prone to sunburn and the harmful long-term effects of UVR. Severe short-term exposure of unprotected, lightly pigmented skin can lead to blistering (a second-degree burn).

There is an association between melanoma and sunburn: if a patient has had more than six serious sunburns, then he or she is at an increased risk for melanoma. Exposure to UVR and the rise of malignant melanomas has led to the development of more effective sunblocking agents. Over time, the incidence of malignant melanoma has increased from 1/1500 people in 1930 to 1/250 in 1980. By the year 2000 the incidence is expected to be 1/150. Sunscreens should be used on a regular basis, be applied at least 30 min before exposure, and have a sun protection factor (SPF) ranging from 15 to 30. Individuals with moderately pigmented skin require about 3 to 5 times more exposure to UVR to induce sunburn inflammation compared with Caucasians, and for individuals with darker skin, 10 times more exposure is required.

5.3 Hydration

Adequate skin hydration is normally provided by sebum secretion and an intact

stratum corneum with its keratinized cells. Several factors can affect skin hydration. Among these are relative humidity, removal of sebum, and age. Each of these factors increases water loss from the skin, leading to dryness and scaling. Application of emollients to the skin replaces the barrier function of lost sebum or decreased evaporative water loss when the relative humidity is low. Retention of water in the epidermal layers after application of a lotion leads to swelling of the skin, which is perceived as smoothness and softness. Often various products are promoted with claims of superiority over others without adequate *in vitro*, *in vivo*, or clinical data. The superiority of oil baths over water baths was found to be only marginal. Twenty minutes after both kinds of bath, skin hydration was increased when measured by water evaporation, electrical conductance, and capacitance. A small but significantly greater amount of water was bound in the skin after the oil bath, whereas no change was seen in evaporation, conductance, or capacitance. Thus, increases in water-holding capacity of the skin after an oil bath may not be of importance. On the other hand, a difference was found in skin-surface lipids, which lasted at least 3 h. This effect is comparable with application of a traditional moisturizing lotion. The authors of this study conclude that because daily use of bath oil is not practical, application of moisturizing lotions may be more advantageous and that the beneficial effects of bath oils are related to lipidization of the skin surface.

5.4 Soaps

Washing or bathing with an alkaline soap reduces the thickness and number of cell layers in the stratum corneum. Generally, soap emulsifies the lipid coating of the skin and removes it along with resident and transient bacteria. Excessive use of soap or detergents can interfere with the water-holding capacity of the skin and may impair bacterial resistance. Use of alkaline soaps increases skin pH, which may change bacterial resistance. The time for recovery to normal skin pH of 5.5 depends on the length of exposure. Ordinary washing requires 45 min to restore skin pH, whereas prolonged exposure can require 19 h. Other agents that can lead to delipidization or dehydration of skin are alcohol and acetone. Currently, acidic skin cleansers appear to be less irritating than a neutral or alkaline one and there is some evidence to suggest that acidic cleansers decrease the number of acne lesions on the face.

5.5 Nutrition

Normal healthy skin integrity can be maintained by an adequate dietary intake of protein, carbohydrate, fats, vitamins, and minerals. Under normal conditions in healthy individuals, increased nutrition is not beneficial if there is adequate dietary intake. If the skin is damaged, increased dietary intake of some substances such as vitamin C for collagen formation may be beneficial. A healthy diet of protein breaks down to supply the necessary amino acids for protein synthesis. Fats are broken down into essential fatty acids, which can then be used by cells to form their lipid bilayer. Carbohydrates are digested to supply energy for cell metabolism. Vitamins C, D, and A; the B vitamins pyridoxine and riboflavin; the mineral elements iron, zinc, and copper; and many others are needed to maintain a normal

healthy skin. Adequate dietary intake can be ensured by ingestion of amounts consistent with the recommended daily allowances (RDA).

5.6 Medications

Various medications affect the skin. Some of the best studied are the corticosteroids, which are known to interfere with epidermal regeneration and collagen synthesis. Photosensitive and phototoxic reactions are also known to occur from medications. Some categories of medications that can affect the skin are antibacterials, antihypertensives, analgesics, tricyclic antidepressants, antihistamines, antineoplastic agents, antipsychotic drugs, diuretics, hypoglycemic agents, sunscreens, and oral contraceptives. Skin flora can be changed by the use of antibacterials, orally administered steroids, and hormones. Analgesics, antihistamines, and nonsteroidal anti-inflammatory drugs (NSAIDs) can alter inflammatory reactions. Thus, whenever drugs are prescribed and skin reactions occur, medications should always be examined to check whether they are responsible.

6 Wound Healing

Healing of skin wounds normally occurs in a predictable sequence of phases including: (1) hemostasis; (2) inflammation; (3) repair (characterized by mitosis, angiogenesis, and synthesis of ECM); and (4) remodeling of the scar matrix (Fig. 3). These processes are regulated by numerous molecules including growth factors, cytokines, chemokines, receptors, proteinases and their inhibitors.

6.1 Hemostasis

The first major event following a skin injury is hemostasis, and the platelets play key roles in this process as they undergo activation, adhesion, and aggregation. These events are triggered by interactions of platelets with both soluble mediators and matrix components. Platelets become activated when exposed to extravascular collagen (such as type I collagen), which they detect via specific integrin receptors in their plasma membrane. Platelet adhesion to collagen activates them to release soluble mediators (growth factors and cyclic AMP) and adhesive glycoproteins from their α-granules, which are in turn, signals for subsequent platelets to change their morphology, become sticky and to aggregate. The aggregated platelets become trapped in the fibrin web and provide the bulk of the clot, and their membranes act as a surface on which inactive clotting enzyme proteases are bound, activated, and then released to accelerate the clotting cascade. The key glycoproteins released from the platelet granules include fibrinogen, fibronectin, thrombospondin, and von Willebrand factor. Soluble mediators released from the α-granules include platelet-derived growth factor (PDGF), transforming growth factor β (TGFβ), transforming growth factor α (TGFα), basic fibroblast growth factor (bFGF), and VEGF. PDGF and TGFβ are chemotactic for neutrophils and monocytes and recruit them from the vasculature to initiate the inflammatory response. VEGF, TGFα, and bFGF act on endothelial cells to initiate angiogenesis. PDGF is also chemotactic for fibroblasts, which will migrate to the area to begin the process of collagen deposition. Thus, through the interaction with the ECM and release of

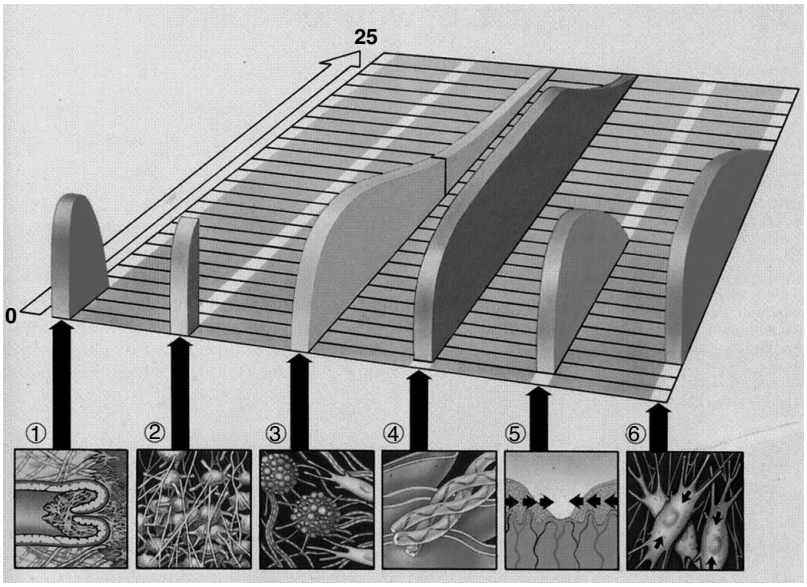

Fig. 3 Time sequences of normal wound healing. After an injury to skin, the vasculature responds (1) immediately by constriction of severed capillaries followed by increased permeability, which lasts for several days. The coagulation (2) cascade rapidly generates the fibrin clot, which forms the ''provisional wound matrix'' that is rich in growth factors released from granules of platelets that are trapped in the fibrin matrix. Inflammation (3) initially involves neutrophils that are draw to the injury by cytokines, followed a few days later by macrophages, which continue to destroy bacteria and release proteases to remove damaged components of the extracellular matrix. After one to two weeks, inflammation subsides unless bacterial contamination persists. Synthesis of new vasculature and extracellular matrix (granulation tissue) repairs the wounded dermal tissue (4), enabling epidermal cells (5) to proliferate, migrate, and resurface the injured area. Myofibroblasts (6) contract the new scar matrix, and eventually the scar remodels (late phase of 4).

soluble mediators, platelets not only contribute to hemostasis but their products also set the stage for the subsequent events of the healing process.

6.1.1 **Provisional Wound Matrix**

An injury that extends into the dermis of the skin causes disruption of the ECM and initiates the clotting cascade. Fibrin is generated at the site of injury when thrombin catalyzes conversion of the plasma-derived fibrinogen to fibrin. The fibrin clot acts to tamponade the bleeding and also to form a temporary scaffolding for the repair process. Serum-derived adhesion proteins, such as fibronectin and vitronectin, subsequently coat the fibrin network, forming a ''provisional wound matrix'' that plays a crucial role in cellular attachment through their interactions with integrin receptors. Fibronectin facilitates the movement of cells into the wound site from the vasculature (such as leukocytes migrating from the vasculature), as well as promoting migration of fibroblasts and

capillary cells through granulation tissue and epithelial cells moving over granulation tissue during resurfacing. The provisional wound matrix of fibrin/fibronectin also serves to bind and store growth factors, which are released by proteases (MMPs and serine proteases) as the provisional wound matrix is replaced by new collagen molecules in the proliferative/repair phase. Initially, type III collagen is synthesized by cells in the wound, which is slowly replaced over weeks and months by type I collagen molecules, which are found in normal skin. Furthermore, during the early phases of scar formation, the collagen molecules tend to be arranged in bundles that are orientated parallel to the edges of the wound rather than the more complex basket weave pattern of collagen bundles, which is characteristic of normal dermis. As the initial scar tissue remodels over many months, the architecture and composition of the scar matrix begins to resemble nonwounded skin, but never fully regenerates nonwounded ECM.

6.2 Inflammatory Phase

6.2.1 Neutrophils

Neutrophils are the first inflammatory cells to respond to the soluble mediators released by platelets and the coagulation cascade. They begin their journey from the vasculature by first adhering to the endothelial cell walls via their surface integrins and then releasing elastase and collagenase, which facilitate their migration through the basement membrane surrounding the endothelial cells and into the ECM at the wound site. Their primary role is to mount the first line of defense against infection by phagocytosing and killing bacteria, and by destroying foreign materials and devitalized tissue. They are able to interact with these extracellular targets via their integrin receptors. Neutrophils also produce and release inflammatory mediators such as TNFα (tumor necrosis factor) and IL-1 (Interleukin 1) that further recruit and activate fibroblasts and epithelial cells. Neutrophils produce and contain high levels of destructive proteases and oxygen free radicals, which they use to digest phagocytized materials. Upon their inevitable death, neutrophils release these substances into the local wound area where they can contribute to extensive tissue damage and prolong the inflammatory phase. The persistent presence of high levels of bacteria in a wound may contribute to chronicity through continued recruitment of neutrophils and their release of proteases, cytokines, and intracellular contents.

6.2.2 Monocytes/Macrophages

Usually, neutrophils are depleted in the wound after 2 to 3 days and are replaced by tissue macrophages. Macrophages begin as circulating monocytes that are attracted to the wound site beginning about 24 h after injury, by both soluble mediators and matrix degradation components such as fragments of collagen and fibronectin. Monocytes bind to the ECM via integrins and immediately differentiate into tissue macrophages. Serum factors and fibronectin mediate this differentiation. Tissue macrophages have a dual role in the healing process. They are voracious phagocytes and patrol the wound area ingesting bacteria, devitalized tissue, and depleted neutrophils. Macrophages also produce collagenases and elastase to assist them in breaking down devitalized tissues. They are able to regulate proteolytic destruction of tissue in the wound by producing and secreting inhibitors for these

enzymes. As important as their phagocytic role, macrophages also mediate the transition from the inflammatory phase to the proliferative phase of healing. They release a wide variety of growth factors and cytokines including TNFα, PDGF, TGFβ, TGFα, IL-1, IL-6, Insulin-like Growth Factor (IGF-1), and FGF. Some of these soluble mediators recruit and activate fibroblasts, which will synthesize, deposit, and organize the new tissue matrix, while others promote angiogenesis.

6.3 Proliferative Phase

Events of the proliferative or tissue building phase of healing include the synthesis, deposition, and organization of granulation tissue, ingrowth of new blood vessels and epithelial migration, proliferation, and stratification. In this phase of healing fibroblasts, macrophages, endothelial, and epithelial cells interact with matrix and with each other.

6.3.1 Granulation Tissue

Granulation tissue is a transitional replacement for normal dermis, which eventually matures into a scar during the remodeling phase of healing. It is characterized from unwounded dermis by its extremely dense network of blood vessels and capillaries, elevated cellular density of fibroblasts and macrophages, and randomly organized collagen fibers. It also has an elevated metabolic rate compared to normal dermis, which reflects the activity required for cellular migration, division, and protein synthesis.

6.3.2 Fibroblasts

The collagen, proteoglycans, and other components that comprise granulation tissue are synthesized and deposited primarily by fibroblasts. Fibroblasts migrate into the wound in response to multiple soluble mediators released by initially platelets and later by macrophages. Fibroblast migration in the ECM depends on precise recognition and interaction with specific components of the matrix. Fibroblasts in normal dermis are typically quiescent and sparsely distributed, whereas, in the provisional matrix of the wound site and in the granulation tissue, they are quite active and crowded together. Their migration and accumulation in the wound site requires them to change their morphology and to produce and secrete enzymes to clear a path for their movement from the ECM into the wound site.

Fibroblasts begin moving by first binding to matrix components such as fibronectin, vitronectin, and fibrin via their integrin receptors. Integrin receptors attach to specific amino acid sequences (such as R-G-D or arginine–glycine–aspartic acid) or binding sites in these matrix components. While one end of the fibroblast remains bound to the matrix component the cell extends a cytoplasmic projection to find another binding site, when the next site is found, the original site is released and the cell uses its cytoskeleton network of actin fibers to pull itself forward.

The direction of fibroblast movement is determined by the alignment of the fibrils in the ECM and provisional matrix and the gradient of chemotactic growth factors, cytokines, and chemokines. Fibroblasts tend to migrate along these fibrils as opposed to across them. Fibroblasts secrete proteolytic enzymes locally to facilitate their forward motion through the matrix. The enzymes secreted by the fibroblasts include three forms of the MMP family – collagenase (MMP-1) gelatinases (MMP-2 and MMP-9), which degrade gelatin substrates and

stromelysin (MMP-3), which has multiple protein substrates in the ECM.

Once the fibroblasts have migrated into the matrix, they again change their morphology, settle down and begin to proliferate and to synthesize granulation tissue components including collagen, elastin, and proteoglycans.

6.3.3 Angiogenesis

Damaged vasculature must be replaced to maintain tissue viability. The process of angiogenesis is stimulated by local factors of the microenvironment including low oxygen tension, low pH, and high lactate levels. Also, certain soluble mediators are potent angiogenic signals for endothelial cells. Many of these are produced by epidermal cells, fibroblasts, vascular endothelial cells and macrophages, and include bFGF, TGFα, and VEGF. It is now recognized that oxygen levels in tissues directly regulate angiogenesis by interacting with oxygen sensing proteins that regulate transcription of angiogenic and antiangiogenic genes. For example, synthesis of VEGF by capillary endothelial cells is directly increased by hypoxia through the activation of the recently identified transcription factor, hypoxia-inducible factor (HIF), which binds oxygen. When oxygen levels surrounding capillary endothelial cells drop, levels of HIF increase inside the cells, HIF-1 binds to specific DNA sequences and stimulates transcription of specific genes such as VEGF that promote angiogenesis. When oxygen levels in wound tissue increase, oxygen binds to HIF, leading to the destruction of HIF molecules in cells and decreased synthesis of angiogenic factors. Regulation of angiogenesis involves both stimulatory factors like VEGF and antiangiogenic factors like angiostatin, endostatin, and pigment epithelium-derived factor (PEDF).

Binding of angiogenic factors causes endothelial cells of the capillaries adjacent to the devascularized site to begin to migrate into the matrix and then proliferate to form buds or sprouts. Once again the migration of these cells into the matrix requires the local secretion of proteolytic enzymes, especially MMPs. As the tip of the sprout from one endothelial cell extends and encounters a sprout from another endothelial cell, the sprouts develop a cleft that subsequently becomes the lumen of the evolving vessel and complete a new vascular loop. This process continues until the capillary system is sufficiently repaired and the tissue oxygenation and metabolic needs are met. It is these new capillary tuffs that give granulation tissue its characteristic bumpy or granular appearance.

6.3.4 Epithelialization

Epithelialization is a multistep process that involves epithelial cell detachment and change in their internal structure, migration, proliferation, and differentiation. The intact mature epidermis consists of five layers of differentiated epithelial cells ranging from the cuboidal basal keratinocytes nearest the dermis up to the flattened, hexagonal, tough keratinocytes in the uppermost layer. Only the basal epithelial cells are capable of proliferation. These basal cells are normally attached to their neighboring cells by intercellular connectors called *desmosomes* and to the basement membrane by hemidesmosomes. When growth factors such as epidermal growth factor (EGF), keratinocyte growth factor (KGF) and TGFα are released during the healing process, they bind to receptors on these epithelial cells and stimulate migration and proliferation. The binding of the growth factors triggers the desmosomes and hemidesmosomes to dissolve so that the cells can detach in preparation for

migration. Integrin receptors are then expressed and the normally cuboidal basal epithelial cells flatten in shape and begin to migrate as a monolayer over the newly deposited granulation tissue, following along collagen fibers. Proliferation of the basal epithelial cells near the wound margin supply new cells to the advancing monolayer apron of cells (cells that are actively migrating are incapable of proliferation). Epithelial cells in the leading edge of the monolayer produce and secrete proteolytic enzymes (MMPs), which enable the cells to penetrate scab, surface necrosis, or eschar. Migration continues until the epithelial cells contact other advancing cells to form a confluent sheet. Once this contact has been made, the entire epithelial monolayer enters a proliferative mode and the stratified layers of the epidermis are reestablished and begin to mature to restore barrier function. TGFβ is one growth factor that can speed up the maturation (differentiation and keratinization) of the epidermal layers. The intercellular desmosomes and the hemidesmosome attachments to the newly formed basement membrane are also reestablished. Epithelialization is the clinical hallmark of healing but it is not the final event – remodeling of the granulation tissue is yet to occur.

6.4 Remodeling

Remodeling is the final phase of the healing process in which the granulation tissue matures into scar and tissue tensile strength increases. The maturation of granulation tissue involves a reduction in the number of capillaries via aggregation into larger vessels and a decrease in the amount of glycosaminoglycans and the water associated with the GAGs and proteoglycans. Cell density and metabolic activity in the granulation tissue drop during maturation. Changes are also made in collagen content and organization, which enhance tensile strength. The tensile strength of a newly epithelialized wound is only about 25% of normal tissue. Healed or repaired tissue is never as strong as normal tissues that have never been wounded. Tissue tensile strength is enhanced primarily by the reorganization of collagen fibers that were deposited randomly during granulation and increased covalent cross-linking of collagen molecules by the enzyme, lysyl oxidase, which is secreted into the ECM by fibroblasts. Over several months or more, changes in collagen organization in the repaired tissue will slowly increase the tensile strength to a maximum of about 80% of normal tissue.

Fibroblasts are the main cell type involved in remodeling. They synthesize new collagen, which is deposited along lines of tension. Initially, wound fibroblasts secrete type III collagen, which is then replaced by type I collagen during remodeling. Fibroblasts also secrete MMPs, which breakdown the type III collagen that was randomly deposited during the proliferative phase. A balance must be maintained between collagen removal and synthesis during remodeling, and this is achieved through the action of enzyme inhibitors like the tissue inhibitors of metalloproteinases that are also produced by fibroblasts.

6.5 Chronic Wounds

As outlined earlier, healing of skin wounds normally occurs in a predictable sequence of phases including: (1) hemostasis; (2) inflammation; (3) repair (characterized by mitosis, angiogenesis, and synthesis of ECM); and (4) remodeling of

the scar matrix. These processes are regulated by numerous molecules including growth factors, cytokines, chemokines, receptors, proteinases, and their inhibitors. It is reasonable to assume that the failure of an acute wound to progress through the phases of healing is due to conditions that interfere with the normal interactions of these molecules. Previous studies that analyzed fluids collected from chronic wounds found elevated levels of inflammatory cytokines, elevated levels of proteinases, and low levels of growth factor activity compared to acute, healing wounds. These observations led to the hypothesis that chronic wounds develop because of prolonged inflammation in acute wounds, which produces elevated levels of proteinases that destroy growth factors, receptors, and ECM proteins that are essential for healing. Furthermore, analysis of fibroblasts cultured from chronic wounds indicate that they frequently have reduced capacity to proliferate in response to specific growth factors. If this hypothesis is correct, it follows that elevated levels of inflammatory cytokines and proteinases should decrease and mitogenic activity should increase in fluids as chronic wounds begin to heal. Several studies have, indeed, reported reduced levels of inflammatory cytokines and proteases and increased mitogenic activity in wound fluids as chronic wounds begin to heal. These results support the concept that treatments that shift the molecular balance in chronic wounds to a pattern that resembles the molecular profile found in acute healing wounds will promote healing.

6.6 Wound Bed Preparation

Wound bed preparation is a comprehensive approach to wound management, which focuses on optimizing conditions in the wound to encourage normal endogenous processes of healing, by removing or correcting the barriers to healing. It is based on an understanding of the underlying molecular and cellular processes that occur in normal wound healing and the differences that have been identified in chronic wounds. The TIME acronym, developed by a group of wound care experts, was useful in focusing on four major attributes of chronic wounds that must be optimized for wounds to begin to heal. As shown in Table 1, the TIME acronym is a practical guide to wound management, which relates clinical observations and interventions to the underlying wound pathology in each of four areas: (1) T for tissue: nonviable or deficient; (2) I for infection/inflammation; (3) M for moisture balance; (4) E for edge of wound, nonadvancing or undermined. Application of the concepts of wound bed preparation has led to an improved dressing that contains collagen (gelatin) and is designed to reduce destruction of essential proteins in wound fluids by proteases in wound fluids by acting as a ''substrate sink.'' A hydrogel containing doxycycline, which is an inhibitor of MMPs as well as an antibiotic, stimulated healing of chronic diabetic foot ulcers. Thus, wound bed preparation is emerging as a useful education aid as well as a practical guide for treatment strategies.

7 Summary

As the body's largest organ, the skin serves several complex functions: protection, thermoregulation, sensation, metabolism, and communication. Numerous factors influence the skin's ability to adequately

Tab. 1 TIME – Principles of wound bed preparation. Wound bed preparation is a comprehensive approach to wound management which focuses on optimizing conditions in the wound to encourage normal endogenous processes of healing by removing or correcting the barriers to healing. The TIME acronym is a practical guide to wound management which relates clinical observations and interventions to the underlying wound pathology in each of four areas: (1) T for tissue: nonviable or deficient; (2) I for infection/inflammation; (3) M for moisture balance; (4) E for edge of wound, nonadvancing or undermined.

Clinical observations	*Molecular & cellular problems*	*WBP clinical actions*	*Effects of clinical actions*	*Clinical outcome*
Tissue management Nonviable or deficient	Defective matrix and cell debris impair healing	Debridement (episodic or continuous) • Autolytic, sharp surgical, enzymatic, mechanical, or biological • Biological agents	Restoration of wound base and functional extracellular matrix proteins	Viable wound base
Infection and inflammation control	High bacteria counts or prolonged inflammation ↑ Inflammatory cytokines ↑ Proteases ↓ Growth factor activity	Remove infected foci – topical/systemic Antimicrobials Anti-inflammatories Protease inhibitors	Low bacteria counts or controlled inflammation ↓ Inflammatory cytokines ↓ Proteases ↑ Growth factor activity	Bacterial balance and reduced inflammation
Moisture balance	Desiccation slows epithelial cell migration Excessive fluid causes maceration of wound	Apply moisture balancing dressings Compression, negative pressure or other methods of removing fluid	Restore epithelial migration, desiccation avoided Edema, excessive fluid controlled, maceration avoided	Moisture balance
Epithelial edge advancement	Nonmigrating epidermal margin Nonresponsive wound cells and abnormalities in protease activities	Reassess cause, refer or consider corrective advanced therapies • Debridement • Bioengineered skin • Skin grafts • Adjunctive therapies	Migrating keratinocytes and responsive wound cells. Restoration of appropriate protease profile in wound	Advancing epithelial margin

provide these functions, such as age, UV exposure, hydration, medications, nutrition, and soaps. Knowledge of the structure and functions of normal skin are important for understanding the processes that occur during normal aging and healing of injuries to the skin. Extensive signaling through autocrine, paracrine, and endocrine pathways by growth factors, cytokines, and proteases occurs by multiple types of cells in wounds to regulate the rate and amount of scar tissue that forms. In addition, interaction of cells with ECM components via integrin receptors further regulates gene expression. When the sequential processes of normal wound healing are disrupted, wound healing is slowed or stopped resulting in a chronic wound. Identification of molecular and cellular abnormalities in chronic wounds provides a targeted approach to correct the abnormal imbalances and promote healing.

1 Introduction

Innovative biotechnologicals of the future include gene transfer medicinal products. It can be assumed that by mid-2003, ~4000 patients or healthy individuals would have been treated within a clinical gene therapy trial, ~600 of those in Europe, and ~260 in Germany (The data originate from some statistics published in the Internet by Wiley Genetic Medicine Clinical Trials Online, http:///www.wiley.co.uk.genetherapy, and are reproduced by courtesy of the publisher.). Most of the clinical trials are currently in phase I or II due to a great diversity of ongoing developments, clinical experience must first be gained, before target-orientated product development and phase III clinical trials can be initiated. In this regard, investigator-driven gene therapy strategies developed by biomedical laboratories together with special clinic teams are very distinct from those developed by pharmaceutical industry. Investigator-driven gene therapy strategies are being invented by teams of biomedical researchers and physicians while developing a new approach for the treatment of a special disease in a defined stage. This is used, for the first time, on a selected group of patients in first clinical trials of phase I/II and aimed at proving the safety of the medicinal product. In clinical trials sponsored by pharmaceutical industry, this phase of orientation has often already been completed and further development in phase II or III is aimed at dose finding or proving efficacy. Concerning product development, there are no standard approaches because, at this stage of development, little experience has been gained and the types of gene transfer medicinal products are very diverse. Therefore, in the following sections, the main current clinical developments will be described while a brief outline of a single example of a manufacturing process is given, also due to manifold diversity.

Gene transfer medicinal products for human use are medicinal products used for *in vivo* diagnosis, prophylaxis, or therapy (Fig. 1). They contain or consist of:

1. genetically modified cells,
2. viral vectors, nonviral vectors or so-called naked nucleic acids, or
3. recombinant replication-competent microorganisms used for purposes other than the prevention or therapy of the infectious diseases that they cause.

The aim of the nucleic acid or gene transfer is the genetic modification of human somatic cells, either in the human body, that is, *in vivo*, or outside the human body, that is, *ex vivo*, in the latter case followed by transfer of the modified cells to the human body. The simplest case of genetic modification of a cell results from addition of a therapeutic gene encompassed by an expression vector. At least in theory, nucleic acid transfer may also be aimed at exchange of individual point mutations or other minimal genetic aberrations. Scientifically, this process is termed *homologous recombination* with the aim of repairing a defective endogenous gene at its locus. In principle, this can be achieved by so-called homologous recombination achieved by transferring oligonucleotides, where – thanks to 5′ and 3′ flanking homology regions – the new correct DNA sequence is replacing the existing defective one. In practice, homologous recombination is technically not yet achievable with the efficiency that will be required for clinical use.

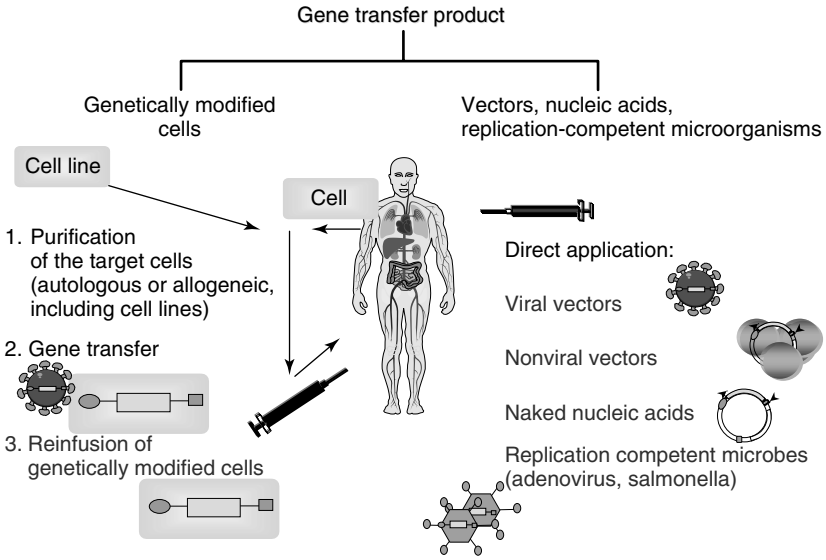

Fig. 1 Gene transfer medicinal products. The gene transfer medicinal products mentioned here are identical with those described in Table 1 of the European ''Note for guidance on the quality, preclinical, and clinical aspects of gene transfer medicinal products (CPMP/BWP/3088/99).'' The definition given is in compliance with the legally binding definition of gene therapeutics in Part IV, Annex I of Directive 2003/63/EC amending Directive 2001/83/EC.

Normally, genetic modification of cells is nowadays achieved by the transfer of an expression vector on which the therapeutic gene is located. The vector is transferred to cells via a delivery system (Fig. 2) such as a viral vector particle, a nonviral vector complex or a plasmid. In the latter case, the expression vector is inserted into and therefore part of a bacterial plasmid, which allows its manufacture and amplification in bacteria. Viral expression vectors contain the sequence signals (nucleic acid sequences) required for transfer by a particular viral vector particle. For retroviral vectors, for example, such signals are encompassed by the flanking ''long terminal repeat'' (LTR) sequences, the packaging signal psi (Ψ) required for incorporation of the expression vector by the retroviral vector particle, and other sequence signals. For nonviral vector complexes and naked nucleic acid, the expression vector is part of a bacterial carrier, the so-called plasmid DNA. Nonviral vectors are, for example, plasmid DNA mixed with a transfection reagent, whereas naked DNA does not contain a transfection reagent.

Another example of a gene transfer medicinal product is a recombinant microorganism such as conditionally replication-competent adenoviruses for tumor therapy. Here, neither is an endogenous cellular gene repaired by homologous recombination nor is a nonadenoviral therapeutic gene transferred. The transfer of conditional replicating adenoviruses to the malignant tumor cells induces cell lysis and local tumor ablation. The entire genome of the adenovirus is transferred without an additional therapeutic gene. The adenoviral genome may therefore be considered as the therapeutic gene.

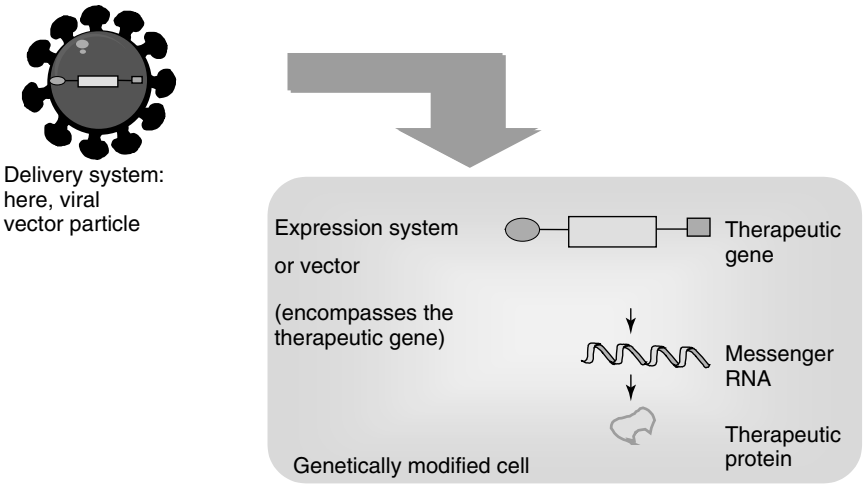

Fig. 2 Delivery system and expression vector used as gene transfer medicinal products. The terminology complies with the definition of gene therapeutics in Part IV, Annex I of Directive 2003/63/EC amending Directive 2001/83/EC.

Gene transfer efficiency plays a central role in gene transfer. It depends on a number of factors, for example, target cell, type of application (*ex vivo* or *in vivo* strategy), the tissue or organ containing the target cells, the physiological situation, and the disease and disease stage. Table 1 shows the most common viral vectors currently in clinical use. The vectors shown are replication incompetent and only transfer the expression vector void of any viral genes as much as possible. So-called integrating vectors mediate chromosomal integration of the expression vector (e.g. retroviral vectors), whereas nonintegrating vectors lead to an episomal status of the expression vector in the cell (e.g. adenoviral vectors), or to its cytoplasmatic replication (e.g. α-virus-derived vectors, vaccinia). Vectors derived from vaccinia, for example, used for tumor vaccination, may be replication incompetent such as modified vaccinia ancara (MVA) or ALVAC or replication competent, but attenuated like vaccinia.

After uptake by human somatic cells, the expression vector is transcribed like a normal cell gene. The resulting messenger RNA (mRNA) is translated and the therapeutic protein is synthesized by the cellular machinery. When so-called ribozyme genes are used, the mRNA acts like a catalytic enzyme and is itself the therapeutic gene product. As already mentioned, when a recombinant microorganism such as a conditionally replication-competent adenovirus (RCA) is used, the genome of the microorganism may be seen as the therapeutic gene.

2 Gene Transfer Methods

The objective of clinical gene transfer is the transfer of nucleic acids for the purpose of genetically modifying human cells (Fig. 3).

Whether a viral, a nonviral vector, or a naked plasmid DNA is used depends on

Tab. 1 Gene transfer methods (vectors/delivery systems).

Delivery system	***Description***	***Chromosomal integration***
Naked nucleic acid	Plasmid DNA, in absence of transfection reagents	No (after im inoculation)
Nonviral vector	Plasmid DNA/transfection reagent mixture	No (application dependent)
Viral vector		
Retroviral vector	Derived from murine leukemia virus (MLV)	Yes
Lentiviral vector	Derived from HIV-1	Yes
Adenoviral vector	Deletions in the virus genes E1, E3 or E4, E2ts, combinations thereof or ''gutted'' (gene-depleted)	No
Conditionally replication-competent adenovirus	No therapeutic gene except for the virus genome	No
Adeno-associated virus (AAV) vector	Wild-type AAV-derived	Yes /no (application dependent)
Smallpox virus vector	MVA (''Modified Vaccinia Ancara'')	No
	ALVAC (''Avian Vaccinia'')	No
	Vaccinia	No
Alphavirus vector	SFV	No
Herpes-viral vector	Herpes simplex virus	No

Note: SFV: Semliki Forest virus; MLV: murine leukemia virus.

the target cell of the genetic modification and whether an *in vivo* modification of the cell is at all possible. For a monogeneic disease affecting immune cells, it is for example, possible to purify CD34-positive cells or lymphocytes from the peripheral blood (e.g. by leukapharesis), to genetically modify the cells in culture, and to return the treated cells. Before reapplication, the treated cells may or may not be enriched. Currently, long-term correction of cells is only possible when integrating vectors such as retroviral or lentiviral vectors are used. Owing to chromosomal integration of the expression vector, the genetic modification is passed on to the daughter cells during cell division and persists. Only long-term expression may still be a problem. For therapy of a monogeneic disease such as cystic fibrosis, the target cells are primarily the endothelial cells of the bronchopulmonary tract, which can only be subjected to *in vivo* modification attempts. Although long-term correction would be desirable, *in vivo* modification using adenoviral vectors appeared to be more promising, because the target cells are largely in a resting state of the cell cycle amenable to adenoviral gene transfer due to expression of the cell surface receptors used by adenoviruses for cell entry. In addition, the amount and titers of adenoviral vectors seemed suitable. These examples illustrate that a number of factors contribute to the choice of the treatment strategy, the vector, and the route of administration. No single ''ideal'' vector is therefore suitable

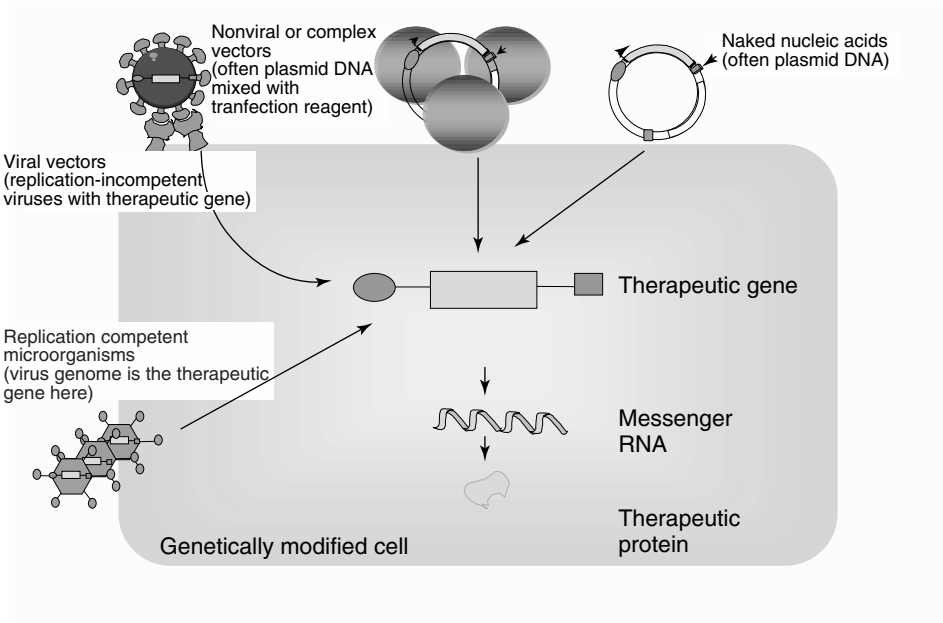

Fig. 3 Delivery systems used in clinical gene transfer. During gene therapy, an expression vector (therapeutic genes) is transferred to somatic cells via a delivery system, for example, a viral or nonviral vector (replication incompetent), a naked nucleic acid, or a recombinant, mostly conditionally replication-competent microorganism. The gene transfer, termed *transfection* when a viral vector is used or termed *transfection* when naked DNA or a nonviral vector is used, leads to genetic modification of the cell. The gene transfer can be carried out *in vivo*, that is, directly in or on the human body, or *ex vivo*, that is, in cell culture followed by the transfer of the modified cells to the human body.

for a large variety of gene therapies. In the past 15 years, many novel gene transfer techniques have been developed and used in clinical studies. In the following section and in Table 1, specific characteristics of the vectors most commonly used in the clinic are summarized.

2.1 Nonviral Vectors and Naked Nucleic Acid

The advantage of nonviral gene transfer systems compared with viral gene transfer systems is the smaller size limitations for the genes to be transferred. The expression vectors are nowadays usually part of a bacterial plasmid that can easily be amplified and grown in bacterial cultures. Plasmid DNA of up to 20 kb pairs encompassing an expression vector of up to 17 kb pairs can easily be manufactured. Promising methods for the *in vivo* administration of plasmid DNA include intradermal or intramuscular injection for the so-called naked nucleic acid transfer. Needle injection or application by medical devices such as gene guns can be used for this purpose. For so-called nonviral vectors, for example, synthetic liposomes or other transfection reagents mixed with plasmid DNA, the DNA-binding liposomes mediate contact with the cellular

plasma membrane thus releasing the DNA into the cytoplasma of the cell where uptake by the nucleus has to occur subsequently. During receptor-mediated uptake of nonviral vectors, cell surface proteins (receptors), for example, asialoglycoprotein or the transferrin receptor, mediate cellular uptake of the DNA complex containing a specific receptor ligand.

2.2 Viral Vectors

During evolution, viruses have been optimized to efficiently enter mammalian cells and replicate. Infected mammalian cells transcribe the viral genes and synthesize the viral gene products with high efficiency, sometimes to the disadvantage of endogenous protein production. Viral vectors are replication-incompetent particles derived from viruses by genetic engineering, which no longer transfer to cells the complete set or any viral genes. Instead, an expression vector with one or more therapeutic genes is transferred to cells. Since no complete viral genome is transferred, virus replication is impossible or, in some cases, it is impaired like with first- or second-generation adenoviral vectors. The following section briefly describes the properties of the current frequently used viral vectors.

2.2.1 Retroviral Vectors

The retroviral vectors in clinical use have mainly been derived from murine leukemia virus (MLV). MLV causes leukemia in mice and replication-competent retrovirus (RCR) in a contaminated vector preparation was shown to cause leukemia in severely immunosuppressed monkeys. RCR absence has therefore to be verified before human use of retrovirally modified cells. MLV vector use *in vivo* has been very rare. The genome of the retroviral vectors consists of two copies of single-stranded RNA, which contains one or more coding regions flanked by the viral control elements, the so-called ''long-terminal repeat'' regions. In the infected cells, the RNA is translated into double-stranded viral DNA and integrated into the cell. The integrated vector DNA is the expression vector. MLV vectors allow efficient genetic modification of proliferating cells by chromosomally integrating the expression vector.

Advantages of retroviral vectors include high gene transfer (transduction) efficiency, and long-term modification of cells due to stable integration of the expression vector into the chromosome of the cells. In addition, the MLV envelope proteins can be exchanged against those from other viruses (which is termed *vector pseudotyping*). This allows preparation of MLV vectors with improved transduction efficiency for certain cell types. Disadvantages of retroviral vectors include the small size of the coding region (~9 kb pairs or less), the restriction of transduction to proliferating cells only, insertional mutagenesis due to integration and the low titer of usually not more than 10^8 transducing units per milliliter of vector preparation. Although chromosomal integration occurs generally at random, it may lead to activation of cellular cancer genes, so-called proto-oncogenes, or, theoretically, to inactivation of tumor suppressor cells. In conjunction with additional genetic mutations, this may result in very low frequency in malignant cell transformation. Hundreds of patients that have been treated with retrovirally modified hematopoietic cells years ago have not shown any signs of cancer related to the gene transfer except for two patients

treated during an SCID-X1 (severe combined immunodeficiency disease) gene therapy trial in France. In the latter two leukemia cases, the vector-mediated overexpression of the proto-oncogene LMO2, possibly in conjunction with the therapeutic γc chain gene (which may influence cell proliferation and signal transduction) and the SCID-X1 disease, are the probable cause of the leukemia (see the following sections).

2.2.2 Lentiviral Vectors

Lentiviral vectors have been derived from human immunodeficiency virus type 1 (HIV-1), simian immunodeficiency virus (SIV) isolated from various old-world monkeys, feline immunodeficiency virus (FIV) and equine infectious anemia virus (EIAV) isolated from horses. Lentiviruses cause an acquired immunodeficiency syndrome and a replication-competent virus has therefore to be excluded before human use by batch-to-batch analysis and verification of the absence of replication-competent lentivirus (RCL). Lentiviral vectors may transfer coding regions of up to 9 kb pairs and allow pseudotyping just like MLV vectors. Their advantage is the dual capacity to transfer therapeutic genes into nonproliferating cells in conjunction with persistent genetic modification due to chromosomal integration. This could be useful for *ex vivo* modification of stem cells and *in vivo* modification of neuronal cells. Most lentiviral vectors have been pseudotyped with the G-protein of vesicular stomatitis virus (VSV-G) or the envelope proteins of Gibbon ape leukemia virus. The first clinical study using lentiviral vectors was started in 2003 and involves the *ex vivo* modification of autologous lymphocytes of HIV-infected patients with a therapeutic ribozyme gene shown *in vitro* to inhibit HIV-1 replication.

2.2.3 Adenoviral Vectors

The adenoviral genome consists of double-stranded DNA that persists episomally, that is, inside the nucleus, but not integrated into the chromosome of the cell. Therefore, the genetic modification may be lost during cell proliferation. Adenoviral vectors are the currently preferred vectors for the *in vivo* transduction of a variety of human somatic cells including nonproliferating cells. In contrast to lentiviral vectors, they allow insertion of larger coding regions of therapeutic genes above 10 kb pairs and are not associated with a detectable risk of insertional oncogenesis. In addition, vector titers above 10^{11} transducing units per milliliter can usually be achieved. The lack of long-term expression is in part due to the fact that certain adenovirus genes have been kept on first or second-generation adenoviral expression vectors, and because of the frequent generation of RCA during production. So-called gutless vectors are void of any adenoviral genes, but have to be purified from RCA after production.

Some wild-type (replicating) adenovirus strains cause inflammations of the airways and the conjunctivae. Adenoviral vectors may therefore also be transferred by inhalation of aerosols and inflammations observed following vector applications are mainly local, transient, and associated with very high titer applications. High-titer adenoviral vectors are no longer systemically administrated, because one patient died during systemic administration of a maximum dose of $\sim 10^{13}$ vector particles during gene therapy of the monogeneic disease OTCOTC (''ornithine transcarbamylase'') deficiency, a life-threatening metabolic disorder.

2.2.4 AAV (Adeno-associated Viral) Vectors

Adeno-associated viruses (AAVs) belong to the family of parvoviruses. Their genome consists of single-stranded DNA. Wild-type AVV can only replicate in the presence of helper viruses like adenovirus or herpesvirus and has not been associated with disease. AAV can infect hematopoietic cells including nonproliferating cells. Integration in infected human somatic cells is often confined to a distinct locus on human chromosome 19. AAV-derived vectors are usually classified as integrating vectors, although vector integration is unfortunately no longer confined to chromosome 19, but absence of integration may be observed, for example, following intramuscular administration The size of the coding region is very limited (~4 kb pairs).

2.2.5 Poxvirus Vectors

Poxvirus vectors encompass vaccinia derived from the smallpox vaccine and more attenuated variants like ALVAC or MVA. Their genome consists of single-stranded DNA of 130 to 300 kb pairs. Replication is restricted to the cytoplasm of cells and high amounts of protein are synthesized by the cell following transduction. Most applications, therefore, involve intramuscular vaccination.

3 Clinical Use

3.1 Overview on Clinical Gene Therapy Trials

A number of clinical trials show promising results (see Table 2). In the past few years, it has become increasingly clear that for each disease, the development of a particular and specific gene transfer method in connection with a particular treatment approach will probably be necessary. The first standard use of an approved gene transfer medicinal product is to be expected within the next seven years since ~1% of the clinical gene therapy studies are in an advanced stage of phase II or phase III clinical trial.

Clinical gene therapy studies have been performed initially in North America and Europe. About 50 clinical gene transfer studies have been registered in Germany, with slightly more than 250 patients that have been treated (http://www.pei.de) (http://www.zks.uni-freiburg.de/dereg.html). A general overview on registered studies is listed on the following Web sites: (http://www.wiley.co.uk/genetherapy, or www.pei.de). In Germany, a public registry has been available since 2004.

Target diseases in most clinical gene therapy trials have been cancer, cardiovascular diseases, infectious diseases such as AIDS, or monogeneic congenital disorders. The vectors most frequently used *ex vivo* are MLV vectors derived from murine leukaemia virus (MLV), whereas vectors derived from adenovirus, pox viruses, and AAV are usually used *in vivo*. A growing number of studies involves the use of nonviral vectors or naked DNA.

3.2 Gene Therapy of Monogeneic Congenital Diseases

The idea underlying gene therapy is the replacement of a defective gene by its normal, functional counterpart; for example, a mutation of the gene encoding the γc chain of the interleukin-2 and other receptors is the cause of the congenital immune disorder SCID-X1.

Tab. 2 Promising clinical gene therapy trials.

Disease	*Therapeutic gene*	*Pharmaceutical form/vector*	*Target cell*	*Remarks*
Human severe combined immunodeficiency SCID-X1	γc Chain gene (e.g. interleukin-2-receptor part)	MLV vector	Bone marrow stem cells *ex vivo*	4 of 1 patient cured, 2 leukemias
PAOD	VEGFgene	Plasmid DNA	Muscle/ endothelial cells *in vivo* (im)	Improved blood flow
Head and neck tumor	Adenovirus genome (cell lysis/apoptosis)	Tumor cell specific replicating adenovirus	p53-Negative tumor cells *in vivo*	Local tumor remission in combination with chemotherapy
Graft versus host disease in donor lymphocyte transfer for leukemia treatment	Thymidin kinase gene of the herpes simplex virus, followed by treatment with Ganciclovir	T cells, MLV vectors	T-lymphocytes *ex vivo*	Successful treatment of host-versus-graft disease
Hemophilia B	Coagulation factor IX gene	AAV vector	Muscle cells *in vivo* (im)	Improved coagulation factor concentration

Note: PAOD: peripheral artery occlusive disease; VEGF: vascular endothelial growth factor; AAV: Adeno-associated virus; MLV: murine leukemia virus.

Owing to this defect, immunologically relevant receptors are unable to mediate the normal differentiation and immune function of lymphoid cells such as T cells and natural killer lymphocytes (NK). Therefore, newborn babies suffering from SCID-X1 have a very limited immune system and must live in a germ-free environment. Their life expectancy is strongly reduced. Conventional treatment, that is, bone marrow transplantation, can provide a cure to a certain extent, but involves a high risk if no HLA haploidentical donor is available. For the latter situation, gene therapy within the framework of a clinical study was considered in France.

In this study, autologous CD34-positive bone marrow stem cells were retrovirally modified to express the functional γc chain gene. T cells and other hemaotpoietic cells derived from corrected stem cells were shown to repopulate the hematopoietic cell compartment, and over a period of up to three years, 11 treated patients, mostly newborns, displayed a functional and nearly normal immune system. This represents the first reproducible cure of a disease by gene therapy.

A leukemia-like lymphoproliferative disease was diagnosed roughly three years after treatment of two obviously cured patients. Treatment had been started at the age of a few months. Subsequent analysis revealed that the leukemia-like disease was indeed caused by the MLV vector; the disease mechanism is termed *insertional oncogenesis* resulting from insertional mutagenesis of the proto-oncogene LMO2 (mentioned earlier). According to current knowledge, up to 50 cells with an integration in LMO2 may have been administered together with the $\sim 10^8$ genetically modified CD34-positive bone marrow cells. Owing to the expression vector integration, the transcription of the LMO2 gene was deregulated and activated. Under normal circumstances, the body can cope with individual cells presenting preneoplastic changes like the one described. In the two treated children, however, further genetic changes must have accumulated to finally result in leukemia. Contributing factors discussed include the effect of the therapeutic γc chain gene, the product of which influences cell proliferation and differentiation, and other so far unknown genetic changes that may have occurred during the massive *in vivo* cell replication. In SCID-X1, the T-cell compartment is completely depleted, and is replenished after gene therapy by differentiation and replication of a few genetically corrected blood stem cells. During this process, genetic aberrations may occur with substantial frequency. However, further analysis will be required to understand the exact cause of leukemia development in SCID-X1 gene therapy. Since hundreds of patients treated with retrovirally modified cells in the past 10 years have not developed leukemia up to now, it is currently assumed that a practical risk of leukemia only exists in SCID-X1 gene therapy.

Gene therapy of hemophilia B also seems promising. Here, AAV vectors encoding a smaller, but functional version of the human coagulation factor IX gene were administered by intramuscular injection. A detectable increase in factor IX plasma concentration was observed. Even repeated AAV injections were well tolerated.

3.3 Tumor Gene Therapy

There are various gene therapy approaches that are being developed for the treatment

of cancer. They are aimed at inhibiting molecular pathways underlying malignant cell transformation. In other cases, tumor cell ablation by directly applying cell-killing mechanisms or, more indirectly, by improving immunological defense mechanisms directed against tumor cells are attempted.

A number of gene therapy studies involving the adenoviral transfer of tumor suppressor genes like p53 have already been performed. This is aimed at reverting malignant cell transformation or at inducing apoptosis. However, transduction following, for example, needle inoculation into tumors has been shown to be limited to a few cells close to the needle tracks. Direct tumor cell ablation by local injection of conditional RCAs in head and neck tumors led to detectable local tumor regression by direct virus-mediated cell lysis, especially when chemotherapy was used in parallel. Here, virus replication improved transduction efficiency *in vivo*. For the treatment of malignant brain tumors, variant herpesviruses have been inoculated into the tumor in order to lyse the tumor cells *in vivo*, especially if prodrugs have been administered that are converted by the viral thymidin kinase gene to a toxic drug.

In addition, a number of clinical approaches have already been tested that led to an improvement of immune recognition of tumors. They involved intratumoral injection of vectors, which transfer foreign MHC genes, such as B7.1 or B7.2, or cytokine genes, for example, interleukin-2 or granulocyte-macrophage colony-stimulating factor (GM-CSF). Here, vaccinia derived vectors such as MVA or ALVAC have often been used. Autologous or allogeneic tumor cells were also modified *ex vivo* by transfer of immunostimulating genes. Promising results have been reported from a phase I-study in which autologous tumor cells were adenovirally modified with the GM-CSF gene and rapidly reinoculated to stimulate antitumor immunity.

3.4 Gene Therapy of Cardiovascular Diseases

Local intramuscular injection of plasmid DNA or adenoviral vectors encoding vascular epithelial growth factor or fibroblast growth factor, both able to induce the formation of new blood vessels, has been used to improve microcirculation in ischemic tissue. Needle injection of plasmid DNA has been used in leg muscle, catheter application, or needle injection was also tried in ischemic heart muscle. The formation of new blood vessels and an improvement in the microcirculation has been observed.

A narrowing of the blood vessels (restenosis) often occurs after coronary blood vessel dilatation by stent implantation. This is probably caused by the proliferation of smooth muscle cells following injuring of the blood vessel endothelium by the stent. Here, the role of adenoviral or plasmid DNA mediated transfer of the gene encoding inducible nitroxide synthase (iNOS) is thought to result in reduced cell proliferation.

3.5 Preventive Vaccination and Gene Therapy of Infectious Diseases

During the past five to ten years, effective medicines have been developed for the treatment of AIDS. Combinations of effective chemotherapeutics are able to inhibit various steps of the replication cycle of HIV-1. This often results in reduction of the viral load in the peripheral blood, sometimes down to a level barely detectable with modern techniques. Because of the

requirement for long-term treatment and the massive adverse effects related to conventional treatment by chemotherapy, gene therapy of HIV infection could offer additional therapy options. *Ex vivo* retroviral transfer of HIV-inhibiting genes into peripheral blood lymphocytes or CD34-positive human cells has been attempted, so far with little success. The therapeutic molecules used include (1) decoy-RNA specifying multiple copies of the Rev- or the Tat-responsive element, so-called poly-TAR or poly-RRE sequences, (2) mini antibodies (single chain Fv; scFv), able to capture viral gene products within the cell, (3) trans-dominant negative mutants of viral proteins, for example, RevM10, or (4) ribozyme RNA, which enzymatically cleaves RNA. Other genes still under development are designed to prevent entry or chromosomal integration of HIV. It remains to be shown whether such gene therapy approaches present a suitable therapeutic option compared with existing chemotherapy.

The best prevention of infectious diseases is achieved by prophylactic vaccines. Clinical trials using vectored vaccines based on ALVAC or MVA have been initiated. Other clinical trials pursue the goal of developing vaccines against HIV-1, malaria, hepatitis B, tuberculosis, and influenza A virus infections. Vaccination regiments using poxvirus vectors such as ALVAC or MVA in combination with naked DNA as a prime vaccine, sometimes followed by further booster injections of recombinant viral antigens, are being tested in humans. Such regiments have been shown to prevent disease progression after lentivirus infection of monkeys. This illustrates the complexity of vaccination strategies that are currently pursued in vaccine research.

3.6 Clinical Gene Therapy for the Treatment of Other Diseases

Clinical gene therapy can also be used for the treatment of diseases not necessarily caused by single known gene defects, if promising therapeutic genes can be reasonably applied. Patients with chronic rheumatoid arthritis, for instance, should benefit from a reduction of the inflammations in joints. Such inflammations are caused or at least maintained by a cascade of events including the overexpression and increased release of a number of inflammatory cytokines. Monoclonal antibodies able to reduce the local concentration of the tumor necrosis factor (TNF) have already been successfully used to treat disease. Here, clinical gene transfer approaches involve the transfer of autologous synovial cells modified *ex vivo* by a therapeutic gene encoding interleukin-1 receptor antagonist. Alternatively, adenoviral vectors with the same gene have been directly injected into the affected joint.

4 Manufacture and Regulatory Aspects

The regulation of gene therapy is very complex and differs considerably in the European Union and the United States. In Part IV, Annex I of Directive 2003/63/EC (which replaces Annex I of Directive 2001/83/EC), a definition of so-called gene therapeutics is given. As gene therapy not only includes therapeutic but also preventive and diagnostic use of vectors, nucleic acids, certain microorganisms and genetically modified cells, the term ''gene transfer medicinal products'' as used in the relevant European guideline ''Note for guidance on the quality, preclinical, and

clinical aspects of gene transfer medicinal products (CPMP/BWP/3088/99)'' seems more exact. An accurate listing of the medicinal products that belong to the group of gene transfer medicinal products can be found in the table contained in the guideline. The definition given in Sect. 1 of this article is in accordance with this guideline and is in agreement with the definition of gene therapeutic products of Directive 2003/63/EC. The annex of the latter Directive contains legally binding requirements for quality and safety specifications of gene transfer products. Although targeted at product licensing, these requirements may have a bearing on their characterization before clinical use. Active ingredients of gene transfer as defined medicinal products may include, for example, vectors, naked plasmid DNA, or certain microorganisms such as conditionally replicated adenovirus. For the *ex vivo* strategy, the active ingredients are the genetically modified cells.

Written approval by a competent authority in conjunction with positive appraisal by an ethics committee will in the future be necessary for the initiation of clinical gene therapy trials. Respective regulatory processes are currently established in all EU member states during transformation of Directive 2001/20/EC. The manufacture of clinical samples in compliance with good manufacturing practice (GMP) will become compulsory. Germline therapy is illegal in the EU. The law relevant for clinical gene therapy trials and manufacture of gene transfer medicinal products in Germany is the German Drug Law (AMG) and respective decrees and operation ordinances. The law governing the physicians' profession stipulates in the ''Guidelines on gene transfer into human somatic cells'' (''Richtlinien zum Gentransfer in menschlichen Körperzellen'') that the competent ethics committee may seek advice from the central ''Commission of Somatic Gene Therapy'' of the Scientific Council of the German Medical Association before coming to its vote. The Paul-Ehrlich-Institut is the competent authority in Germany and offers information on current clinical trial regulations.

Gene transfer medicinal products will be licensed via the centralized procedure by the European Commission. The licensing process is coordinated by the EMEA (''European Agency for the Evaluation of Medicinal Products'') following submission of a licensing application. The marketing authorization is governed by Council Regulation (EC) No. 2309/93. The recommendation in favor or against marketing authorization is made on the basis of Directives 75/319/EEC and 91/507/EEC by experts of the national competent authorities which are members of the ''Committee for Proprietary Medicinal Products'' (CPMP).

In the United States, the Center for Biologics Evaluation and Research ''(CBER) of the ''Food and Drug Administration'' (FDA) is responsible for clinical trial approval and marketing authorization.

The assessment of the licensing application focuses on the quality, safety, efficacy, and environmental risk of a gene transfer medicinal product. The manufacturing process has to be designed and performed according to GMP regulations. Like other biologicals, gene therapy products have considerably larger size and complexity compared to chemicals, and analysis of the finished product is not sufficient to control their quality and safety. A suitable process management, in-process control of all critical parameters identified within process validation are decisive factors. Gene transfer medicinal products

containing or consisting of genetically modified organisms are also subject to contained use regulations before licensing and until these organisms are applied to humans.

From the economic point of view, procedures for the manufacture of therapeutic DNA must be scalable and efficient, and at the same time simple and robust. Manufacturing processes are as manifold as the gene transfer methods used in gene therapy. As an example, manufacture of plasmid DNA for naked nucleic acid transfer can be briefly described as follows. The methods available for plasmid production today largely originate from lab procedures for the production of DNA for analytical purposes (mini preparations) and have been adapted to fit process scale. Toxic substances and those that present a hazard to the environment, expensive ingredients, and nonscalable methods must be avoided. In this context, the experience gained from industrial manufacture of raw materials with the aid of bacterial cultures and virus production for the purpose of vaccine production are useful for fermentation. Suitable methods for downstream processing above all include chromatographic methods with high

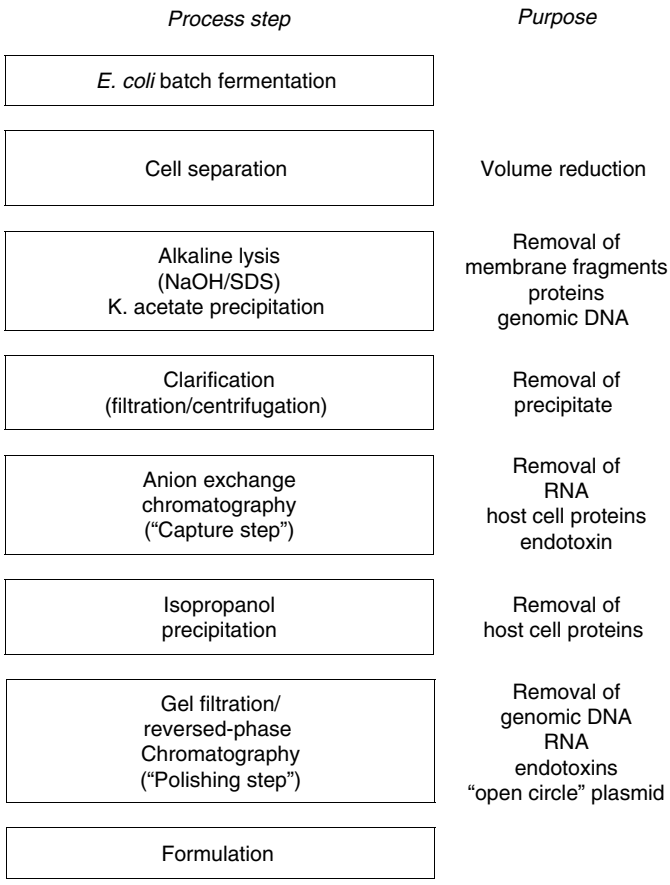

Fig. 4 Therapeutic plasmid DNA: typical manufacturing process.

Test	*Specification* (*method*)
Appearance	Clear colorless solution (visual inspection)
Size, restriction interfaces (identity)	Agreement with plasmid card (agarose gel electrophoresis, restriction enzyme assay)
Circular plasmid DNA (ccc)	>95% (Agarose gelelektrophorese, HPLC)
E. coli DNA	<0.02 µg/µg plasmid DNA (southern blot)
Protein	Not detectable (BCA protein assay)
RNA	Not (Agarose gel electrophoresis)
Endotoxin	<0.1 EU/µg plasmid DNA (LAL assay)
Sterility	No growth after 14 days (USP)
Specific activity	Conforms to reference standard (*in vitro* transfection)

Fig. 5 Therapeutic plasmid DNA: typical release specifications.

dynamic capacity and selectivity as well as high throughput.

In a typical procedure for the manufacture of therapeutic plasmid DNA (cf. Figs. 4 and 5), the first step is batch fermentation of *Escherichia coli* cells from a comprehensively characterized ''Master Working Cell Bank'' (MWCB). For this purpose, modern methods use high-density fermentation with optimized and safe *E. coli* K12 strains bearing a high number of copies of the required plasmid. The bacterial cells are harvested for further processing, resuspended in a small buffer volume, and lysed in an alkaline lysis procedure. By neutralization, the plasmid DNA is renatured while a large quantity of proteins, membrane components, and genomic DNA remain denatured. After separation of the precipitate by filtration, a chromatographic step can be performed as ''capture step.'' Because of the anionic character of the nucleic acid, anion exchange chromatography (AEX) is the method of choice. In fractionated gradient elutions, differences in the charge enable the separation from contaminated RNA. Gel filtration (GF) or reversed phase (RP) steps can be used for fine purification. For final product analysis, evidence must be provided batch by batch that besides the correct identity and homogeneity, critical impurities like microorganisms, host cell proteins, genomic DNA, RNA, or endotoxins have been reduced below the specified limits. Removal of endotoxins is critical for *in vivo* gene transfer efficiency achieved with naked DNA.

Some established methods from protein chemistry can be used for processing therapeutic DNA. In parallel with the processing of proteins, however, the fact cannot be concealed that nucleic acids have some very specific properties. These include the extremely high viscosity of DNA solutions, the high sensitivity of nucleic acids to gravity, the low static and dynamic capacity of their chromatographic adsorption, and the ability to penetrate filtration media with porosities well below their molecular weight (''spaghetti effect'').

After first experience, plasmid concentrations of $\sim$200 mg L^{-1} fermentation broth can be obtained in high-density fermentation (optical density >50), corresponding to an yield of $\sim$800 mg plasmid DNA per kg of dry biomass. Thus, from a fermenter of 1000 L usable volume, $\sim$100 g plasmid DNA can be isolated per run in a batch fermentation at a purification yield of $\sim$50%. Consequently, capacities for production of kilogram amounts can be built up with existing technologies.

5
First Experience with the Clinical Use of Gene Transfer Medicinal Products

The development of somatic gene therapy is still in its infancy. A number of theoretical risks of gene therapy have been listed, and numerous approaches and gene transfer methods are being developed in the clinic, even more in preclinical experiments.

In spite of this, a few SCID patients have been apparently cured by gene therapy using retrovirally modified bone marrow stem cells. At the same time, the occurrence of leukemia in two of the ~10 successfully treated children showed that theoretical risks cannot be clearly distinguished from clinically relevant risks due to the so far insufficient clinical experience. Trends, however, show that each pathological situation will require the development of a certain adapted gene therapy approach. Thus, in the long run, gene therapy will present real therapy or prevention options, especially for a number of up to now insufficiently treatable or untreatable diseases.

Keywords

Axis
It defines the polarity of an organism in various directions, for example, anteroposterior or apical–basal.

Bilateria
Multicellular animals comprising three germ layers (ectoderm, mesoderm, and endoderm). Their body plans are characterized by an anteroposterior and a dorsoventral axis, which is genetically controlled by gene clusters. Many structures occur in pairs.

Body Plan
Organization of an organism according to an axis.

Diploblasts
Animals comprising two germ layers (ectoderm and endoderm).

Metazoa
Multicellular animals composed of specialized cells that share labor.

Morphogenesis
A process that describes the formation of organs in a developing embryo.

Pattern
Entities of tissue units that are arranged during development in a well-ordered spatial pattern of cell activities.

Porifera (Sponge)
The phylogenetically oldest metazoan phylum, which evolved first from the common ancestor of all multicellular animals, the Urmetazoa.

Segments
Similar tissue units that are simultaneously formed during embryogenesis and arranged along an axis. These elements are remodeled during the development.

Serial Modules
Similar tissue units that are arranged along an axis and are formed in succession. These modules of the animals remain morphologically mostly unchanged during their development to adults.

Somites
Tissue units that are arranged along an axis and are formed consecutively. These elements are morphologically changed during development.

Triploblasts
Multicellular animals comprising three germ layers (ectoderm, mesoderm, and endoderm).

All metazoan animals comprise a body plan of different complexity. Since it is well established – especially on the basis of molecular and cell biological data – that all metazoan phyla, including the Porifera (sponges) evolved from a common ancestor, the fundamental common principles of pattern formation in Metazoa have been studied to a great extent. Common to all metazoan body plans is the formation of at least one axis that runs from the apical to the basal region; examples for this organization step are the Porifera and the Cnidaria (diploblastic animals). Animals belonging to the triploblasts, the Protostomia (model systems: insects and nematodes) and the Deuterostomia (mammals), comprise in addition to the anteroposterior axis also a dorsoventral axis that runs at a right angle to the first. Body plan formation starts from totipotent germ cells that lose their plastic differentiation propensity during their proliferation/differentiation. In the course of the developmental processes, a differential expression of cell–cell and cell–matrix adhesion molecules proceeds, which also involves the formation of cell junction molecules. After formation of tissue units, immune molecules are expressed, which allow the discrimination between self and nonself (establishment of the individuality), a process that is also controlled by apoptotic regulatory systems. Subsequently, extracellular solute factors (morphogens) and other secreted molecules in concert with transcription factors establish the axes. Organizer regions are formed which are localized in diploblasts (Porifera and Cnidaria) in the oscule or mouth region, respectively. In triploblasts, as it is well documented in the vertebrate

Spemann organizer or Hensen's node, cells are formed in a distinct region, which displays the property to induce a complete body axis. In parallel, skeleton formation (exo- or endoskeleton) supports the body construction.

The major difference in the genetic systems controlling body plan patterning between diploblasts and triploblasts lies in the fact that only the triploblasts (both Protostomia and Deuterostomia) comprise clusters of homeotic genes. In diploblasts, those clusters are missing and nonclustered paired-class genes and LIM/homeodomain genes control pattern formation. In metazoans, in diploblasts as well as in triploblasts, body plan formation starts by polarization of the embryo; the subsequent development is followed in diploblasts only to the stage of serial module patterning, while in triploblasts, the development to the adults includes compartmental and the subsequent segmental patterning.

1 Introduction

The multicellular animal kingdom of Metazoa comprises approximately 30 phyla that, as has been elucidated recently, share one common ancestor, the Urmetazoa; this term has now been widely adopted. Contrary to the metazoan organisms, in colonies of animal cells, for example, in choanoflagellates, there is no division of labor. In Metazoa, the cells have been differentiated to perform a series of functions, like digestion, sensation, contraction, and secretion. The determination of metazoan cells to a distinct fate occurs through an alteration in the pattern of gene activity and thus allows a specification to distinct roles. The result of such specialization is that nutrients are taken up by distinct feeding cells and from there are transported to nonfeeding cells, which accomplish different functions. Specialized cells are the basis for pattern formation, a process during which a spatial and temporal pattern of cell activities is organized within the well-ordered organism. Most animals are characterized by a bilateral symmetry and comprise regulatory genes, which are involved in head formation. Metazoa are grouped into the morphologically more diverse bilaterians, which themselves are further subdivided into Protostomia, including Ecdysozoa and Lophotrochozoa, and Deuterostomia and the nonbilaterian metazoans (phyla Porifera, Placozoa, Coelenterata, and Ctenophora).

During pattern formation a body plan is established, which also defines the main axes of the multicellular animal. From Porifera to Arthropoda (Protostomia) and Vertebrata (Deuterostomia) the level of complexity of the axes (anteroposterior ends (oral–aboral polarity), dorsal–ventral sides) increases. The two phyla Porifera and Coelenterata that possess only two epithelial layers, the ectoepithelium surrounding the body and the endoepithelium that encloses the digestive cavity(ies), are termed *diploblastic animals* and are defined by one apical–basal polarity. The triploblastic, bilaterian animals are composed, in addition to these external layers (the ectoderm and the endoderm) of a middle, mesodermal, cell layer that originates usually from the endoderm. Pattern formation can be studied during embryogenesis

or during differentiation of embryonic cells, for example, in three-dimensional cell cultures. These morphogenetic processes are based on and controlled by differential spatial and temporal expressions of genes that initiate or maintain a large number of signaling pathways. Activation of a specific pathway can determine the character of a specific region as in the embryonic organizer, like the ''Spemann organizer'' or the ''Nieuwkoop center.'' In recent years, it has been established that the function of their key signaling pathways act by negative regulation. The tuned interactions result, for example, in the frog blastula/gastrula stages, in a sequential activation of the centers; like in the Nieuwkoop center in the ectoderm of late blastulae, which releases signals required for the activation of the Spemann organizer in the mesoderm of the gastrulae. This example shows that the timing and position of such centers is crucial and allows the synchronization of developmental processes, which drive the correct organization of the future tissue in an organism.

Segmentation (a process during which very similar functional units along a body axis are formed almost simultaneously (in insects)) or somite formation (the units along a body axis are formed sequentially (in vertebrates)) is a feature of triploblastic organisms. Each segment/somite is arranged along the anteroposterior axis. The orientation is controlled by characteristic sets of genes; for example, in insects the parasegments are delimited by the function of the *pair-rule* genes and the subsequent segments by the *segment polarity* genes. In these triploblasts, each segment/somite has its own identity, which is defined by master regulatory genes, termed *homeotic selector* genes. These homeotic genes are arranged into gene clusters. In diploblasts, Coelenterata and Porifera, ancestors of these genes exist as single molecules. It remains, however, enigmatic by which mechanism the organization of the gene clusters present in triploblasts evolved from the single gene of the diploblasts.

In the past few years, it has been elaborated that the Porifera (sponges) as the phylogenetically oldest metazoan phylum comprise already the basic structural and functional elements required for the construction of a body plan; they evolved approximately 800 million years ago. According to the inorganic composition of their skeleton (the elements of their skeleton are termed *spicules*), sponges are grouped into the classes of Demospongiae and Hexactinellida, which possess hydrated, amorphous, noncrystalline silica spicules and the class Calcarea, whose skeletal spicules are formed from calcium carbonate. The Demospongiae and Hexactinellida are the only two taxa within the kingdom of Metazoa which primarily utilize silica instead of calcium in their mineral skeleton; calcium is otherwise the dominant inorganic skeletal component in Metazoa.

Like in the second phylum of the diploblasts, the coelenterates, also the sponges are built from two major epithelial layers. In sponges, the exopinacoderm (formed by exopinacocytes) represents the external epithelium that delimits the organism toward the environment and the endopinacoderm (endopinacocytes), which lines the aquiferous canals. The water flow is directed from the lateral surface of the specimens, through the porocytes and the canals to the lacunae and the choanoderm (choanocyte chambers); Fig. 1. These chambers are composed of two kinds of epithelial cell layers, formed by choanocytes (flagellated cells) and by cone cells (cells with a double-conical shape which hang into the

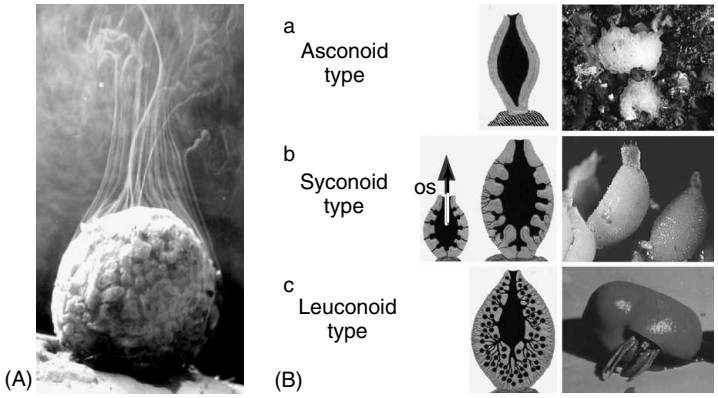

Fig. 1 Body plan organization in the phylum Porifera. (A) Sponges, here *Tethya lyncurium*, have the potency to conduct water from the external milieu through their inhalant openings at the surface to the exhalant apertures, the oscules. This highly complex aquiferous system is formed from differentiated somatic cells, which interact in a tuned manner through cell–cell/cell–matrix interaction. The water flow through a specimen has been visualized with fluorescein; the pulsatory extrusion of the water current can be seen. (B) The three different organization/body plan patterns of sponges are shown in the middle panel. The choanoderm layer is in red and the pinacoderm layer is in blue. (a) In the asconoid type, the sack-like organization shows an unfolded choanoderm. (b) In the syconoid type, the folding of the choanoderm layer results in the formation of choanocyte chambers, which are connected with the incurrent canals. After passing the chambers, the excurrent canals lead the water current to the oscule (os). (c) The organization of the leuconoid type. This complex canal network is composed of discrete choanocyte chambers, connected with a network of incurrent and excurrent canals. In all three types of body organization, a basal site (attachment to the substratum) and an oscular/apical pole (oscule; opening at which the central cavity which is connected with the excurrent canals extrudes the water) exists, which determines the axis (arrow). Representative species of the different organization levels are shown: (a) *Clathrina coriacea*, a calcareous sponge of the asconoid type. Magnification x0.2. (b) A syconoid type of organization as in *Sycon raphanus* (Calcarea); x3. (c) *Suberites domuncula* a siliceous sponge (Demospongiae) of the leuconoid type; x0.5. (See color plate p. xxvi).

chamber formed by choanocytes). Therefore, these chambers can be considered as organ-like assemblies. The function of the choanocyte chambers as organs or organ-like assemblies is to orient the water flow unidirectionally from the incurrent to the excurrent canal to allow the extrusion of the water from the body through the exhalant oscule(s). The two epithelial layers of the sponges surround the mesohyl, which comprises differentiated cells that interact in a coordinate way. In this central body of the sponges, the cells are loosely embedded in a ground matrix, composed primarily of collagen, galectin, and glycoconjugates. This matrix surrounds motile archaeocytes, which are pluripotent, and other differentiated cells, for example, the collencytes and lophocytes, which are involved in the formation of collagen as well

as the sclerocytes that form the spicules. In addition, myocytes exist which allow contraction of the sponge body upon mechanical irritation.

According to the folding pattern of the two epithelial layers of the pinacoderm, in correlation to the choanoderm, three types of sponge complexity are distinguished; the asconoid, the syconoid, and the leuconoid type. The folding of the choanoderm allows the formation of spherical chambers, the choanocyte chambers of different structural degrees (Fig. 1). In the asconoid type, the lateral opening(s) direct the water current to the continuous layer of choanocytes which face the single atrium and then to the oscule (Fig. 1B-a). This type of organization is seen in some Calcarea, for example, *Clathrina coriacea*. In the syconoid type, the folding pattern forms choanocyte chambers and the water flow enters the sponge through the porocytes into choanocyte chambers through which the water is pressed into the atrium and finally via the oscule again to the external milieu (Fig. 1B-b). This type of organization is seen in Calcarea and Demospongiae; as an example the calcareous sponge *Sycon raphanus* is shown here. The leuconoid type derives from the syconoid type of organization (Fig. 1B-c). Here, the porocyte openings lead from the vestibule to the connecting incurrent canals and into the choanocyte chambers. Subsequently, the water current is pressed into excurrent canals that open into the atrium and leaves the organism via the oscule (Fig. 1B-c). Most sponge species, like the marine (siliceous) demosponge *Suberites domuncula* (Fig. 1B-c) show the leuconoid type of organization. The Hexactinellida have an organization pattern that is reminiscent of the syconoid type and are composed of a choanoderm syncytium.

By molecular biological techniques – in the meantime over 15 000 ESTs (expressed-sequence tags; http://spongebase.geno-serv.de) have been elaborated from the sponge *S. domuncula* – and subsequent identification of the functions of sponge genes, it has been disclosed that the basic strategies of body plan formation and of gene expression patterns found in Porifera are characteristic of Metazoa in general. Furthermore, an *in vitro* 3D-cell culture system, termed *primmorphs*, was established. Primmorph cultures are a newly developed technique to grow sponge cells *in vitro*; their cells have the potency to proliferate and to differentiate. This system allows an understanding of the roles of the morphogenetic and pattern-forming genes. The outcome was: first, Porifera are the phylum that is most closely related to the common ancestor of all metazoans, the Urmetazoa; and second, their body plan is controlled by pathways that remained conserved from Porifera to the crown taxa, human or *Drosophila melanogaster*/*Caenorhabditis elegans*. Amazing is the finding that the complexity of the sponge genome, which comprises over 100 000 genes, is high, and that sponge sequences share a high similarity to vertebrate genes. Therefore, it can be proposed that the developmental regulatory genes/proteins present in Porifera are representative of the related molecules found in higher metazoan taxa. The major distinction between Porifera and Cnidaria/Ctenophora on one side and the Bilateria on the other is the number of distinct tissue layers (diploblastic vs. triploblastic animals); Fig. 2.

In the following sections, the different aspects of pattern formation of Metazoa are highlighted, referring to the Porifera as the model organism for multicellular animals.

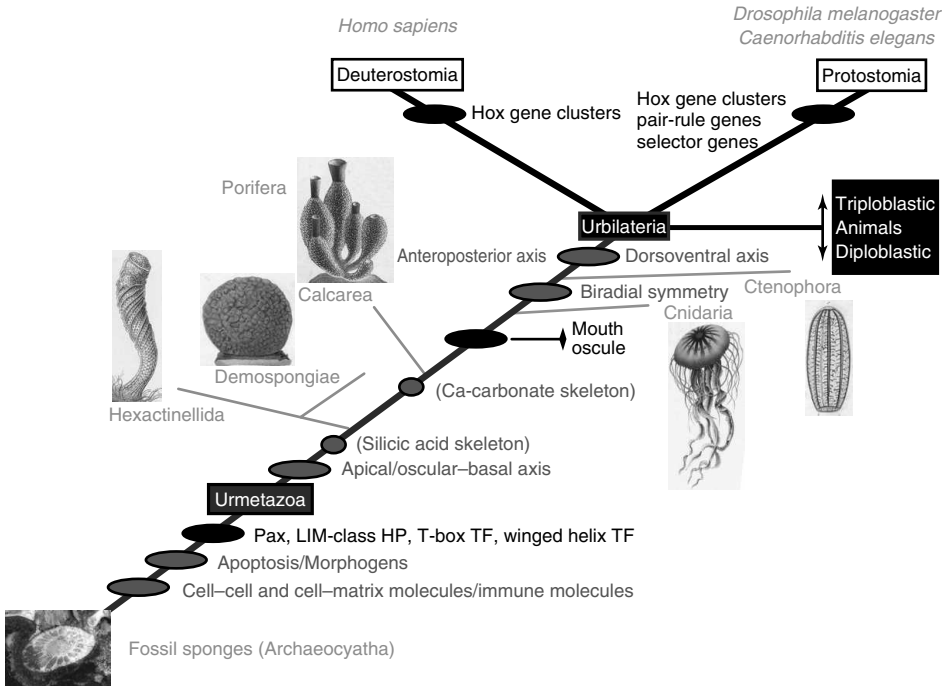

Fig. 2 Phylogenetic position of the Porifera within the metazoan kingdom. As first branches, the three poriferan classes (Hexactinellida and Demospongiae emerged and finally the Calcarea) evolve for the common ancestor of all metazoan phyla, the Urmetazoa. The major evolutionary novelties, which have to be attributed to the Urmetazoa, are those molecules that mediate apoptosis, control morphogenesis, the immune molecules, and cell adhesion molecules. The three classes of Porifera are the model systems that comprise a genetic reservoir of pattern formation characteristic of Metazoa; for example, the transcription factors, like paired box homeodomain molecules, LIM-class homeodomain, T-box (Brachyury) or winged helix (Forkhead). As a sister group to the Calcarea, the Cnidaria evolved. Subsequently, the Ctenophora emerged, which comprise not only an oral/aboral polarity but also a biradial symmetry. In the Cnidaria, the paired box transcription factors have been identified. Finally, the Urbilateria developed from the diploblasts (two epithelial layers), which are built from three germ layers (triploblasts). They diverged into the Protostomia, with the crown species *D. melanogaster* and *Caenorhabditis elegans*, and the Deuterostomia with the humans. Within the triploblastic animals, the homeobox genes are arranged in clusters. (See color plate p. xxvii).

2
Basis of Metazoan Pattern Formation

2.1
Stem Cells

Multicellular animals are characterized by the existence of a series of differentiated somatic cells, in addition to the totipotent germ cells. During evolution from the lowest metazoans, the sponges, to the crown taxa the number of distinct cell types increased steadily. The different somatic cells types derive from the zygote through the respective stem cell stage; the differentiation processes proceed in niches, which form a microenvironment in which

defined expression patterns of signaling molecules and local environmental factors direct the fate of the cells. These niches modify their regulatory properties in response to a changing environment to ensure that stem cell activities meet the needs of an organism for a given differentiated cell type. Two major types of stem cells derive from the zygote; the ''germline'' stem cells and the ''somatic'' stem cell. While the germline stem cells retain their total differentiation capacity, these properties are restricted in the somatic stem cells, which gradually lose their stem cell propensity. However, recent studies indicate that this traditional view of an irreversible loss of the stem cell ability during maturation of somatic cells might not completely reflect the physiological situation. It appears that such fixed ''points of no return'' do not always exist, but that at all levels of differentiation from the pluripotent progenitor cells to the committed progenitors, to the lineage progenitors, and finally to the terminally differentiated cells the propensity to act as a stem cell is retained, even though with a decreasing propensity. In consequence, the differentiation lineages of somatic cells are dynamic and plastic, and the strong distinction between embryonic stem cells and adult stem cells should be reconsidered.

With this new stem cell concept, one can ask for the simplest models of metazoan stem cells. The systems of choice are those organisms that already comprise a body plan organization and that reproduce sexually. These criteria are fulfilled in sponges. It was first discussed in sponges that some lineages of their somatic cells might not have lost the property of re- and transdifferentiation, a finding that became only increasingly obvious in higher metazoans approximately during the last five years.

It is generally agreed that the archaeocytes are the toti-/pluripotent cells in sponges from which the other cells originate; recently, evidence was presented indicating a localization of archaeocytes not only within the mesohyl but also in the endopinacoderm layer. Archaeocytes give rise to the major classes of differentiated somatic cells, (1) the epithelial cells, pinacocytes, and choanocytes; (2) the cells forming the skeleton, collencytes, and sclerocytes; and (3) the contractile cells, myocytes (Fig. 3). It had been operationally outlined that the sperm and egg cells derive from the archaeocytes. It appears that in Porifera the archaeocytes give rise not only to the different somatic cells (epithelial-, skeletal-, and contractile cells) but also to the germ cells from which the embryos originate. Another line of differentiation of the archaeocytes is to the thesocytes, the totipotent cells of gemmules, which are asexually propagative dissemination bodies. Pinacocytes, collencytes/sclerocytes and myocytes are cells with a low stem cell propensity, implying that these somatic cells are ''terminally'' differentiated.

In order to underline the view that the metazoan stem cell concept can also be applied for Porifera, characteristic marker genes have been cloned from *S. domuncula*. The first cDNAs identified whose deduced proteins share sequence similarity to mammalian stem cell markers, were the mesenchymal stem cell-like protein (MSCP) and noggin. MSCP is present in mesenchymal human stem cells; experimental evidence exists that MSCP is expressed in osteogenic mesenchymal stem cells. Functional studies revealed that in sponges the expression of this gene is under positive control of the morphogenetic inorganic elements, silicon, and ferric iron. In addition, two further potential genes

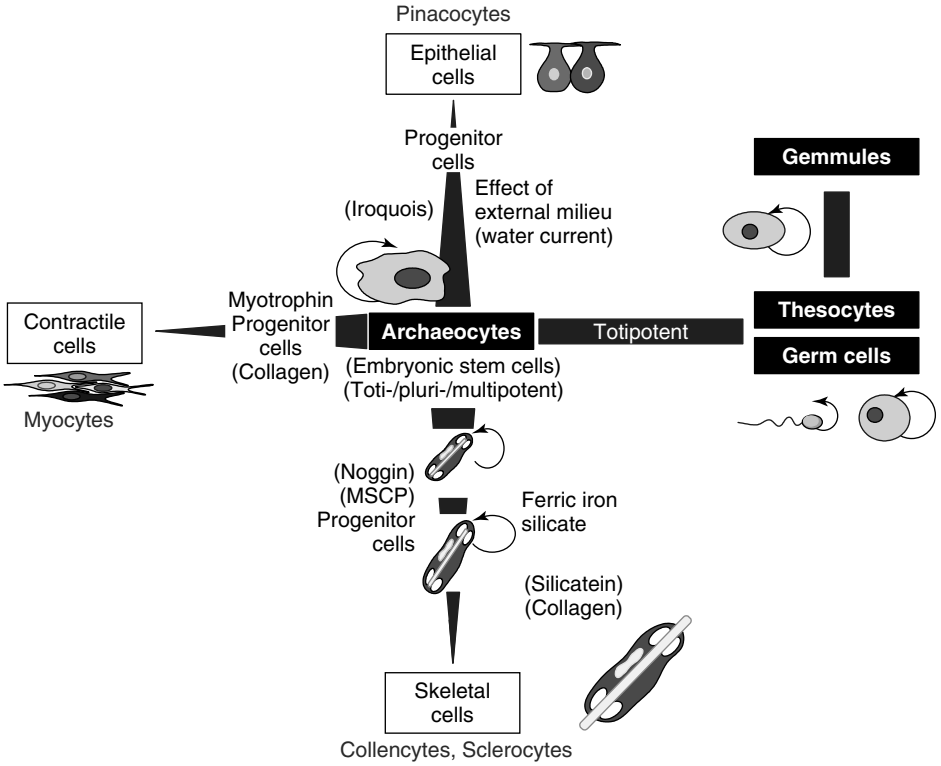

Fig. 3 Sponge stem cell system. Schematic outline of the development of the toti-/pluripotent sponge embryonic stem cells, the archaeocytes, to the germ cells on one side and to the three major differentiated cell types, the epithelial-, the contractile-, and the skeletal cells. It is indicated that during these transitions progenitor cells characteristic of these lineages have to be passed. The (potential) factors, for example, noggin and the mesenchymal stem cell–like protein (MSCP) on the path to the skeletal cells, which trigger the differentiation, are shown. In addition, it is outlined that committed progenitor cells are formed, which respond to the silicate/Fe(+ + +) stimulus through differentiation to skeletal cells, the sclerocytes (= skeletal cells). Without losing the high level of stem cell propensity, the archaeocytes change to germ cells and also to thesocytes, the dominant cells in gemmules (asexual propagation bodies). The triangles schematically indicate the decrease in stem cell propensity during the differentiation process.

involved in the differentiation of stem cells in sponges were isolated; noggin and the glia maturation factor. Noggin is a glycoprotein that binds bone morphogenetic proteins (BMP) selectively and antagonizes their effects. It was initially isolated from Xenopus and found to be expressed in the Spemann's organizer. In vertebrate development, noggin is involved in the formation of dorsal mesoderm derivatives, for example, the skeletal muscles.

In the initial phase of formation, the *in vitro* 3D-cell primmorph system contains predominantly the toti-/pluripotent archaeocytes, which can be stimulated to differentiate into four main tissue-specific directions. If they are induced by the

inorganic factors silicate or ferric iron, the archaeocytes give rise to the skeletal cells through an increased expression of genes encoding the structural proteins silicatein and collagen; a process that is mediated by noggin and MSCP (Fig. 3). Second, if archaeocytes are exposed to a morphogen (myotrophin), they are directed toward the contractile cell lineage. A third lineage, which gives rise to the aquiferous canal system, is induced by a physical factor; there *Iroquois* gene expression is induced as a result of an increased water current, which is paralleled with the formation of canal-like pores in the primmorphs. In higher metazoans, the expression of the *Iroquois* genes is thought to confer identity to a particular region, and hence it can be classified to the homeotic selector genes. The early function of *Iroquois* in insects includes the definition of the eye and notum territories, and in vertebrates, it includes the formation of the neural ectoderm. Late functions of *Iroquois* are subdividing the territories; the dorsal–lateral subdivision in *Drosophila* notum and the patterning of notum bristles and wing veins, and in vertebrates, the subdivision of neural tube and heart patterning. The sponge *S. domuncula* contains in its genome an *Iroquois* gene, which not only has remarkable sequence similarity with those sequences described from triploblastic animals but also expresses it during the formation of one major morphogenetic remodeling process, the construction of the aquiferous canal system (Fig. 3).

In general, toti-/pluripotent stem cells have the potential for extensive proliferation coupled with a high degree of differentiation capacity. The stem cells give rise to somatic cells that are – to a large extent – restricted to their differentiative and regenerative potential. The key role of the stem cells is to establish and maintain tissue homeostasis. The character of the stem cells and also of the differentiated somatic cells depends both on direct adhesion/contact to the adjacent cells and also on solute factors.

2.2 Cell-to-cell Adhesion

For more than 100 years, sponges have been a classical model for basic studies to understand metazoan cell–cell adhesion. Primarily, the marine demosponges *Microciona prolifera*, *Geodia cydonium*, and S. domuncula are the most thoroughly studied species.

2.2.1 Aggregation Factor

In 1973, it had been a success to isolate and purify both from *M. prolifera* and *G. cydonium*, the first extracellular particle termed *aggregation factor* (AF), which promotes the species-specific aggregation of sponge cells (Fig. 4). The AF was characterized as high molecular–weight complexes, which are assembled from a series of proteins that are bound to the core structure both covalently and noncovalently. The AF that mediates cell–cell aggregation depends on the presence of Ca^{2+} and binds to the membrane-associated aggregation receptor (AR).

The molecules in the very complex and dynamic cell–cell and cell–matrix recognition in sponges have been obtained by molecular cloning, for example, the galectin gene as the first cell–cell adhesion molecule, and integrin as the first cell–matrix adhesion receptor in *G. cydonium*. These sponge molecules are closely related to those proteins known to promote adhesion in Protostomia and Deuterostomia. Sequence analyses of the galectin from *G. cydonium* revealed that those amino acid (aa) residues that are involved

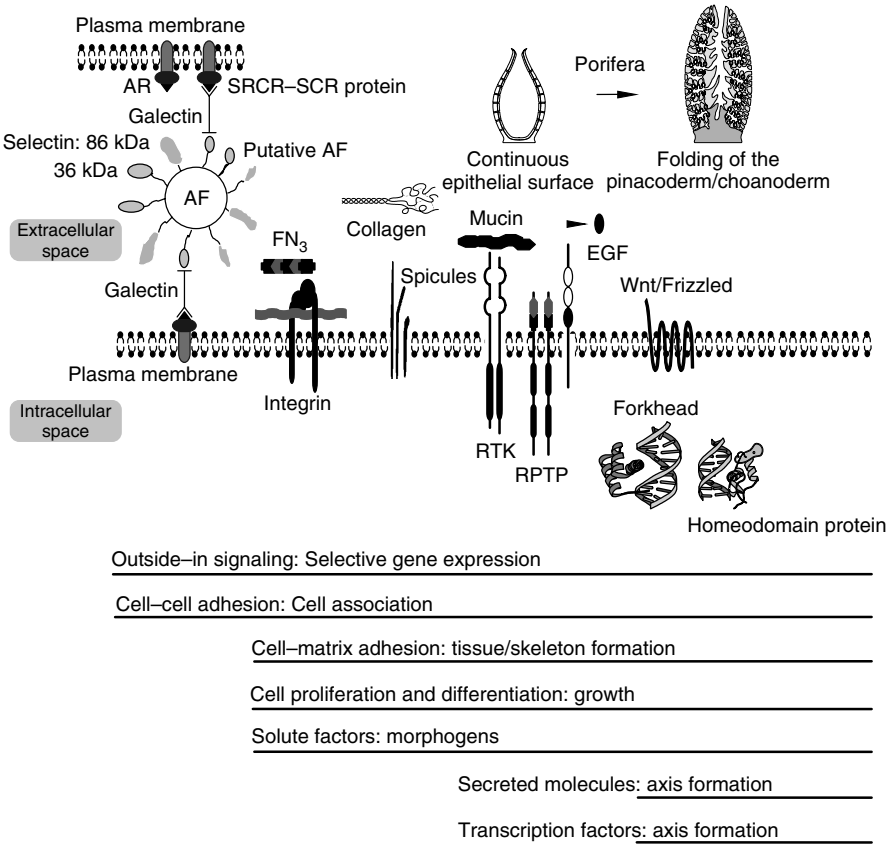

Fig. 4 Different phases required for the initiation of pattern formation (schematic model based on studies on the demosponges *Geodia cydonium* and *Suberites domuncula*). First, cell–cell and second cell–matrix adhesion molecules allow the mechanical interaction between adjacent cells or cells and extracellular matrix molecules. Aggregation factors (AF) in the extracellular space interact with aggregation receptors (AR) and mediate the first mechanical contact. The AF and the AR are complexes that are held together by protein–protein or protein–glycoprotein interactions. The AF-mediated cell–cell recognition is species-specific and very likely controlled by the complex SRCR/SCR-AR, which is embedded in the plasma membrane. Third, after this primary AF-AR-AF contact, intracellular signal transduction pathways are activated, resulting in a selective gene expression. New insertion of adhesion receptors into the plasma membrane follows; for example, integrin and other receptors, involved in tissue and skeleton formation. Like those, the receptor tyrosine kinases (RTK) and the receptor protein-tyrosine phosphatases (RPTP) also are uniquely found in Metazoa. Together with these receptors their ligands are synthesized, for example, collagen, molecules containing the fibronectin FN_3 modules, or mucinlike molecules, which establish the cell–matrix adhesion system. During this phase, growth factors are synthesized, for example, the precursor and the mature epidermal growth factor (EGF), which interact with the newly synthesized receptors. Fourth, solute molecules that initiate axis formation are released. Fifth, after completion of these phases pattern formation can start, a process that is controlled by ''morphogenetic'' cell surface receptors, like Frizzled, and by transcription factors, for example, Forkhead. Also, LIM-class homeodomain transcription factors are activated. It is suggested that in parallel with the expression of these gene cascades, the complexity of the sponge body plan, as an example, increases (upper right).

in binding of galectins from mammalians to galactose are also conserved in the sponge sequence. The sponge galectin is one polypeptide that is associated with the adhesion system in sponges; it links this AF complex to the membrane-associated aggregation receptor. These molecular biological and cell biological findings have been taken as one major clue for the now established view that Metazoa, including Porifera are of monophyletic origin with Urmetazoa as the hypothetical ancestor; Fig. 2.

2.2.2 Aggregation Receptor

The putative AR was cloned from *G. cydonium* and found to comprise fourteen SRCR domains, six SCR repeats, a C-terminal transmembrane domain and a cytoplasmic tail. More recently, one further molecule of the AF complex in the *G. cydonium* system was characterized, which showed a distant relationship to amphiphysin. Interestingly, the AR displays high sequence similarity to the macrophage type I scavenger receptor, macrophage M130 antigen and complement factor I, further supporting the fact that the adhesion molecules are highly conserved from Porifera to Chordata.

The AF and the corresponding AR are not merely adhesion molecules but also cause activation of signal transduction pathways resulting in an increased cell metabolism and also a higher cell proliferation and cell differentiation. The most obvious testimony for these properties can be deduced from the fact that single cells from sponges are not able to divide. Only if cell–cell contact is allowed do they form the 3D-cell cultures, the primmorphs, which contain both proliferating and differentiating cells.

2.3 Cell-matrix Interaction: Tissue Formation

Like in most metazoans, in sponges also the dominant molecule present in the extracellular matrix (ECM) that functions as a cell–matrix adhesion molecule is collagen. The genes were cloned both from the freshwater sponge *Ephydatia muelleri* as well as from *S. domuncula*; the sponge collagens belong to the short chain collagens. In protostomians as well as in deuterostomians, collagen binds to the cell surface receptor integrin. As a first nonbilaterian integrin, the sponge molecules have been identified in *G. cydonium* as well as in *S. domuncula* and the function was partially characterized. A second ligand for the integrin receptors is fibronectin, from which the FN_3 module has been identified (Fig. 4).

In addition, a series of further membrane receptors are required for tissue homeostasis and the subsequent pattern formation. Cell surface–spanning receptors, in particular, the single- (1-TMR) as well as the seven-pass transmembrane receptor proteins (7-TMR), serve as receivers for extracellular signaling molecules. Also, these molecules could be identified in sponges and represent autapomorphic characters for all Metazoa. The sponge1-TMR, the receptor tyrosine kinase (RTK), comprises the following segments; the extracellular domain (ligand-binding domain), the transmembrane domain, the juxtamembrane domain, and the catalytic domain. Its expression is upregulated during tissue fusion processes of autografts. The extracellular domain is composed of two immunoglobulin (Ig)-like segments, closely related to mammalian immunoglobulins, which are also polymorphic in the sponge molecule. The RTK interacts

with a mucin (Fig. 4). The corresponding dephosphorylating receptor, the receptor protein-tyrosine phosphatase (RPTP), was identified in *G. cydonium*. As a 7-TMR, the metabotropic glutamate/GABA-like receptor, a neuronal receptor, was characterized in *G. cydonium*; it responds to extracellular agonists as well as antagonists known from metabotropic glutamate/GABA-like receptors present on nerve cells from mammals. Another 7-TMR, the Frizzled receptor, has been found in *S. domuncula*. We will refer to it later, as a component of the Wnt signaling pathway.

Adhesion receptors, for example, integrins; or cell surface receptors, for example, RTKs, are evolutionary novelties and are found only in Metazoa. These molecules are more than merely mechanical linkages between structural molecules of the ECM and cells, collagen integrin, or other extracellular ligands and receptors, for example, mucin-RTK. During mechanical interaction between the extracellular molecule and the cell surface receptor, the receptor is activated; either, the receptor dimerizes or undergoes a conformational change and becomes enzymatically active, or both. It is amazing how manifold this interaction at the outside region of the cell surface receptor can be. The integrin receptor heterodimerizes with α- and β-subunits. Both subunits comprise a family of different molecules; hence, the number of possible combinations between the individual members is huge. Depending on the dimer formed the subsequent intracellular second messenger generation is different. This so termed *outside-in* signaling through cell surface receptors is also characteristic of 1-TMRs, for example, in RTKs. If an RTK interacts with an extracellular specific stimulus from outside, it undergoes dimerization resulting in a binding-induced conformational change; it then becomes enzymatically active and couples specifically with intracellular pathways. Determined by the members involved in the ligand–receptor complex, different outside-in signaling processes are activated that cause the initiation of a specific gene expression program.

2.4 Cell Junction Molecules

Formation of tight connections between cells is imperative to establish and maintain the tuned interaction between cells in a developing metazoan embryo or tissue. Such connections can be based on direct cell–cell interactions or on solute molecules (morphogens) and also on hormones. Cell junction molecules give the mechanical support for epithelial sheets, function as permeability barrier and, more importantly, provide communication pathways between adjacent cells. Several classes of junctions have been developed in Metazoa; ''occluding junctions,'' which seal cells together in an epithelial cell sheet allowing the formation of a selective permeability barrier (e.g. tight junctions), ''anchoring junctions,'' which mechanically attach cells through the actin- or intermediate filament network (focal contacts, desmosomes), and ''communicating networks'' (gap junctions, synapses). The tight junctions seal adjacent cells in a specific way, allowing the transport only of selected nutrients across a given cell sheet. Tight junctions in the epithelia allow the formation of an intraorganismic milieu, which is different from the external one and maintain this homeostasis. Especially for aquatic organisms, the selective-barrier function of cell sheets was one prerequisite for the formation of integrated multicellular animals. Hence, it was not surprising to find that this form

of junctions, that is, tight junctions, is evolutionarily conserved from sponges to the triploblastic crown species.

As in other metazoans, the tight junction scaffold proteins from sponges comprise the characteristic scaffold protein, a membrane-associated guanylate kinase with inverted arrangement (MAGI; Fig. 5). The sponge MAGI scaffold protein comprises six PDZ domains that are involved in protein–protein interaction, two WW domains that bind to proline-rich peptide motifs, and the conserved guanylate kinase motif. In addition, the existence of one tetraspan receptor, tetraspanin, in *S. domuncula* has been demonstrated. The tetraspanins belong to a group of hydrophobic proteins, comprising four transmembrane domains with a series of conserved aa residues in the extracellular loops. By *in situ* hybridization it had been shown that the *MAGI* gene is highly expressed in the epithelial cell layer and in the cells surrounding the canals; again, this result also shows that from sponges to higher metazoans, the basic requirements for tissue and subsequent pattern formation exists.

2.5 Morphogens

Pattern formation can be caused by a regional/segmental expression of a given gene; the protein formed acts in this region usually in a ''yes'' or ''no'' manner. In addition, morphogenesis can be driven by morphogens. These soluble factors are synthesized at very restricted sites and diffuse from there under formation of a smooth concentration gradient. Cells arranged along this morphogen gradient

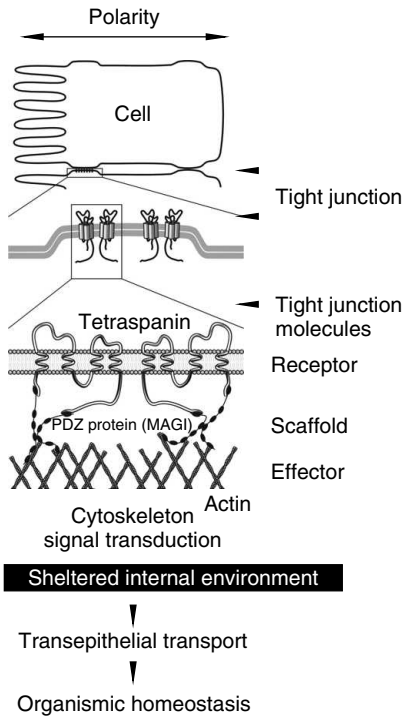

Fig. 5 Elements of tight junction proteins (here from *S. domuncula*). This scheme shows the molecules that seal the epithelial cell layer to control the lateral-extracellular transport in the aqueous milieu. By formation of tight junctions, cells undergo polarization. The tight junctional cell membrane–spanning receptors, here tetraspanin, associate with the scaffold protein, the PDZ protein MAGI. The scaffold protein MAGI plays a crucial role in the organization of the membrane receptor molecules and the effector molecules; the latter compose the cytoskeleton and the signal transduction molecules. Finally, tight junctions allow organismic homeostasis to occur.

react to it in a threshold-like manner. The decrease of the morphogen concentration provides the cells with positional information to which they can respond depending on their genetic program. The consequence of these specifying parameters, concentration, and genetic predisposition (activation of transcription factors), is that sharp distinctions arise in an initially uniform population of cells. Morphogens have been identified in all taxa studied and also in Porifera, for example, myotrophin (Fig. 4).

Myotrophin was first found in mammalian systems; in cardiac myocytes, it stimulates protein biosynthesis, suggesting a crucial role in the formation of cardiac hypertrophy. In *S. domuncula*, the gene encoding myotrophin has been found to multifold stimulate protein synthesis and induce growth of primmorphs to an elongated, oval shape. Furthermore, it could be demonstrated that in the presence of recombinant myotrophin, the cells upregulate the expression of the collagen gene. It is worth noting that the highest myotrophin gene expression is seen in the region of the oscule.

Recently the epidermal growth factor (EGF) was identified in *S. domuncula*. In chordates, EGF interacts with a series of different RTKs resulting in a regionally different cell response. In order to prove if EGF causes a differential gene expression in tissue depending on the regions from where the samples were taken, parabiosis studies were performed. Tissue samples were taken from the oscule region and the basal region of *S. domuncula* (Fig. 6a) The two tissue samples (oscule-basis) were placed together and attached with nylon fibers (Fig. 6b); between the two tissue samples, affi-gel blue beads were interspersed (Fig. 6c). The beads remained uncoated (controls) or were coated with recombinant EGF. After an

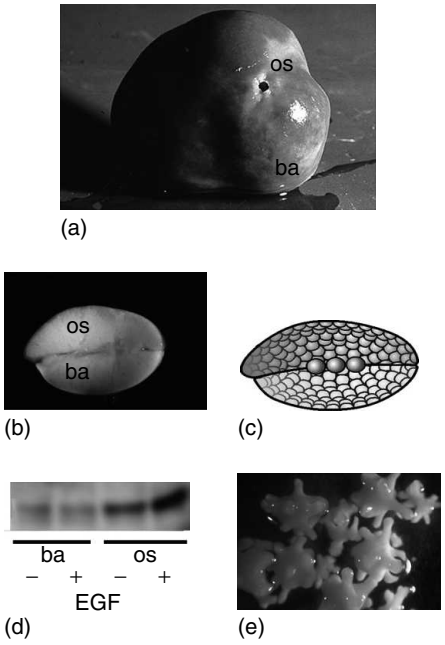

Fig. 6 Morphogenetic activity of the epidermal growth factor (EGF) in the homologous sponge system. (a) A specimen of *S. domuncula* with the pronounced oscule (os), the organizational center of sponge; below the oscule an atrium opens, a cavity where the excurrent canals meet; x2. (b) Tissue samples from the surface of the oscule region (os) and the basis (ba) of an animal tied together with nylon fibers; x2. (c) Between the two caps beads were interspersed, which remained either untreated or were coated with recombinant EGF. (d) After a 24-h incubation period, extracts from the oscule (os) and the basal region (ba) were prepared and equal amounts of protein were determined for the level of Brachyury by Western blotting. (e) Incubation of primmorph for three days in the presence of EGF; the shape of the primmorphs changed from round/oval to lobular; x2.5. (See color plate p. xxiii).

incubation period of 24 h, both the oscule and the basis tissue sample were taken, homogenized and the level of the morphogenetically active transcription factor Brachyury was determined by Western blotting (Fig. 6d). The results show that the expression level of Brachyury in untreated controls (without Brachyury) is low in the basal region of the sponge, in comparison to the level determined in the oscule region. After incubation with recombinant EGF, the level in the basis remained unchanged while it strongly increased in the sample region from the oscule. This finding indicates that predominantly cells from the oscule region have the ability to respond to EGF, while cells from the other region remain silent. As a direct proof that EGF causes oscule-like processes, primmorphs were incubated with low concentrations of recombinant protein for three days. During that period, the round/oval-shaped primmorphs changed to a lobular morphology (Fig. 6e). These data suggest that EGF comprises a morphogenetic potential that leads to the formation of oscules in the described homologous system.

Endogenous retinoids can be considered as morphogens that are involved in the suppression of head formation and activation of expression of posterior-specific genes in amphibians. A retinoid-responsive transcription factor, the retinoid X receptor (RXR), was identified in *S. domuncula*, as well as other elements of the retinoic acid pathway, for example, the ß,ß-carotene-15,15′-dioxygenase. The sponge RXR comprises two motifs of nuclear hormone receptors that exist exclusively in metazoan proteins: the DNA-binding (hormone receptor) domain including its zinc finger modules, and the ligand-binding domain. Functional studies revealed that the expression of the *S. domuncula* RXR undergoes strong upregulation in response to treatment with retinoic acid, while the expression of the sponge caspase is not increased. The gene encoding the morphogenetic LIM/homeobox protein was found to be strongly upregulated in response to retinoic acid treatment. These data indicate that the RXR and its ligand retinoic acid play a role in the control of morphogenetic events in sponges.

2.6 Immunity, Individuality, and Apoptosis

The early metazoans, the hypothetical Urmetazoa, lived in an aquatic environment and consequently were exposed to a massive load of both pro- and eukaryotic organisms trying to invade and destruct them. To cope with these threats, sponges have developed an efficient chemical defense system as well as humoral and cellular defense mechanisms.

The property to distinguish between self–self and self–nonself by fusion or rejection is common to all metazoans. The finding that the strategies used during these histo-(in)compatibility reactions are very similar from Porifera to Chordata was again very surprising. Key molecules involved in allo/autoimmunity in sponges that share high sequence and functional similarity with those molecules that had been found to control historecognition in deuterostomes, have been identified. Among those are the molecules comprising polymorphic Ig-like domains present in the sponge adhesion molecules, the allograft inflammatory factor (a sponge cytokine) as well as the (2–5)A system (control of infection).

Functionally connected with the immune system in Metazoa is the process

of apoptosis. In the last five years, it was again disclosed that the basic apoptotic response and effector systems are conserved among all metazoan phyla. On the basis of the view that developmental processes can only function if they are paralleled with apoptosis, a comprehensive search for molecules in sponges that were involved in apoptotic pathways was initiated. As the most promising segment to screen for a proapoptotic molecule, we selected the death domain, which is found in the mammalian apoptosis controlling proteins Fas, tumor necrosis factor-α or its receptor, and FADD. This approach was successful; the molecule isolated from *G. cydonium* even comprises two death domains. Functional assays were performed with allografts from *G. cydonium*, which revealed that in rejecting tissue a strong increase of the expression of the death domain–comprising gene occurs.

In vertebrates, the death domain containing receptors/adapter molecules interact intracellularly with the caspase-8 proenzyme through the death-effector domain with a similar region in the caspase. An adapter-mediated oligomerization causes an activation of the procaspase(s) that undergo cleavage and subsequently, dimerization. Upstream caspase(s) then process procaspase-3, which after dimerization activates a factor necessary for a proapoptotic DNase to degrade chromatin into the nucleosomal fragments, a hallmark of apoptosis. In Bilateria, a series of caspases are involved in the tuned control of apoptosis starting with caspase-8 in the cascade and ending with caspase-3. One gene has been identified in sponges (*G. cydonium*), which encodes two transcript forms, both for caspase-8 and for -3 equivalents. Functional studies indicate that the two forms of the sponge caspases act in *G. cydonium* in the apoptotic pathway.

In line with the biological evidence that in sponges apoptosis can be initiated by environmental stress factors, for example, bacterial load or cadmium, an intense screening for members of the Bcl-2 family was started. This effort resulted in the cloning and functional analysis of the antiapoptotic/cell survival proteins from the two sponge species. The proof that the sponge gene product acts as a cell survival protein was performed by transfection studies using mammalian cells. It could be shown that transfection of mammalian cells with the sponge *Bcl-2*-related gene confers resistance against heat shock and growth factor deprivation.

Taken together, the bulk of evidence confirms that from sponges to the higher metazoans a complex immune and apoptotic machinery exists, which allows the elimination of unwanted tissue (e.g. in allotransplantation) and the establishment of an organized Bauplan.

3 Skeleton

3.1 Morphogenesis

Morphogenesis is a process that is restricted to multicellular organisms. Like in plants, in animals also the cells are not merely a collection of randomly distributed cell types. During development, differentiated cells precisely associate to tissue, organs, and finally to the organism. In embryogenesis, first a proliferation phase takes place, which is paralleled by the differentiation and the morphogenesis phases (Fig. 4); these processes are driven by controlled gene expression patterns. Characteristic genes/proteins involved in proliferation are, for example,

DNA polymerase or thymidine kinase. Under the control of morphogenetic factors, specific cell surface receptors are expressed, which induce the organization of the intracellular signal transduction molecules, which are then used to allow the expression of extracellular matrices or other specific cell interacting molecules. These events establish differential cell affinities between differentiated cells and provide the basis for cell-specific adhesion and motility. The genes encoding morphogenetic switch proteins establish the formation of an apical–basal or anteroposterior polarity axis.

In all metazoans, a mouth region is formed, which allows the ingestion of food or elimination of metabolic end products. In Coelenterata and higher metazoans, the mouth region is characterized by the existence of an organized nerve net or a central nervous system; the mouth region forms a head and allows active feeding behavior. In Porifera, as the basal metazoan phylum, a mouth *sensu strictu* does not exist since they do not have a nerve system. However, these species also have one organizational center, which shows properties reminiscent of the mouth. There, the excurrent canals meet in a lacuna that opens to the external milieu through the oscule. Moreover, in the oscule region morphological singular structures exist, for example, a contractile rim, which allows the contraction of the oscule and hence influences feeding behavior. The oscule reacts to changes in the environment by contracting or opening and hence, it is provided with key control molecules for food uptake and respiration. Therefore, it can be proposed to consider the oscule as an apical center. This view is also supported by the fact that in the oscule region a high expression of morphogenetically active molecules (organizer molecules), for example, of characteristic homeobox genes, can be monitored.

The morphogenetic proteins establish a developmental gradient and act as transcription factors, morphogens, or signaling molecules. In all metazoans, at least one organizing gradient exists, which originates from a distinct region around the mouth, primarily during embryogenesis. This region was termed *organizer*. Organizer-specific genes include transcription factors and homeobox genes, and also soluble and secreted factors that are involved in cell-to-cell signaling in the extracellular space, and either inhibit or induce growth factor action.

In all metazoans, a dramatic and complex rearrangement of cell assemblies/tissue occurs, which is especially obvious during gastrulation. In a narrow sense, embryonal gastrulation is restricted to Coelenterata and triploblasts that have been conventionally attributed to be composed of the two/three germ layers. However, in view of recent molecular biological studies, it became overt that the Porifera are also provided with the basic elements for the formation of germ layers, which include the ECM (collagen and other adhesion molecules) or the cell–cell junctions (tight junction). Until now, the remaining controversial issue has been the lack of a conventional nerve system in Porifera; however, as outlined in the following, impulse conduction in Porifera might be mediated by their spicule/skeletal system. Genetic experiments revealed that Nodal, BMP, and the Wnt pathway, as well as transcription factors like Forkhead are key elements of germ layer formation and gastrulation. The latter two programming and pattern-forming factors act from Porifera to Bilateria.

The head/apical center regions are characterized by the expression of morphogenetically inductive molecules and hence by the ability to form axes. These centers display organizing functions whose effectiveness drops with distance from them. From Porifera to the triploblastic crown species, these centers display a distinguished regeneration capacity that cannot usually be reached by other regions in the body; removal of these centers can only poorly be replaced by cells from other parts of the body.

Finally, morphogenesis also implies that stage-specific parts of the body are eliminated in order to replace these unnecessary cells by others that are required for the formation of new structures and tissue during development. In recent years, it could be established that the genes and the expressed proteins, which control this apoptotic process, are conserved from sponges to human. In this respect, it is noteworthy to mention that the antiapoptotic protein Bcl-2 from the sponge *G. cydonium* confers resistance against apoptotic stimuli to human cells.

Skeletal elements are formed in all metazoan phyla to stabilize the body and to allow growth. In triploblasts, two different strategies have been followed. In Protostomia, an exoskeleton (integument), especially well developed in Arthropoda/Antennata, is formed which is made of organic molecules (chitin). Growth of the segmentally arranged integument is controlled by pair-rule, segment polarity, and selector genes. In Deuterostomia, and similarly in somites, arranged skeleton is formed during development. There, the skeletal structures (bones) derive from the somatic mesoderm and can be divided into three lineages that generate the skeleton. First, from the sclerotome the axial skeleton derives, then the lateral plate mesoderm generates the limb skeleton, and finally the cranial neural crest gives rise to the branchial arch and craniofacial bones. Osteogenesis involves two processes; the transformation of preexisting mesenchymal tissue into bone tissue (intramembranous ossification), and the differentiation of mesenchymal cells into cartilage, which is subsequently replaced by bone (endochondral ossification). Somite formation occurs along the anteroposterior axis and is controlled by Hox gene clusters and additionally by a series of soluble factors, for example, BMPs or insulin-like growth factors. The matrix macromolecules of the bones comprise the insoluble framework of collagen, which is associated with noncollagenous proteins. Around this matrix the inorganic calcium hydroxyapatite crystals are deposited. The growth of bones follows highly organized patterns; either the bone forming cells are arranged through the collagen matrix in concentric/cylindrical structures or in parallel arrays. Hence, the biomineralization process is guided by organic structural proteins. It should be noted here that biomineralization in various forms around an organic matrix is among the triploblasts not restricted to Deuterostomia, but also occurs in Protostomia, for example, in mussel shells as aragonite (calcium carbonate).

In diploblasts, in coelenterates, the basic inorganic biomineral is calcium carbonate. Especially in corals, the growth pattern has been studied in detail and revealed that around the axis a radiating accretive growth process occurs. This implies that layers of newly formed organic/inorganic material are added to the tip of the preceding growth step. By this process, the thickness of the layers is highest around the central axis and decreases

toward the side of the tip. In analogy to bone formation, the ''apposition'' of new layers of organic/inorganic material occurs through the guidance of organic matrices and the morphogenetically determined body or limb axis. It is outlined later that also in Porifera such an appositive growth pattern is seen.

Taken together the basic processes that allow the formation of a metazoan organism, are cell–cell adhesion, which is followed by cell–matrix adhesion. Then cell proliferation and differentiation occur, which allow growth of the embryo during development. Axis formation is established either by secreted molecules, for example, morphogens, or by transcription factors. This sequential process is schematically outlined in Fig. 4.

3.2 Spicule Network in Sponges: A Unique Skeleton

In living organisms, four major groups of biominerals exist; (1) iron compounds, which are restricted primarily to Prokaryota; (2) calcium phosphates, found in Metazoa; (3) calcium carbonates, used by Prokaryota, Protozoa, Plantae, Fungi, and Metazoa; and (4) silica (opal) present in sponges and diatoms. It is surprising that the occurrence of silica as a major skeletal element is restricted to some unicellular organisms and to sponges (Demospongiae and Hexactinellida). At present, it is not known why sponges have used silica as the biomineral to form one major innovation during the evolution from Protozoa to Metazoa, the hard skeleton. Since the transition from Protozoa to Metazoa is dated back 600 to 1000 million years ago, it has been proposed that oxygen level, temperature, and seawater chemistry played a major role in the evolution from Protozoa to Metazoa. In particular, it was assumed that during the period of the appearance of sponges, the ocean was richer in sodium carbonate than in sodium chloride; and that such a ''soda ocean'' had probably a pH above 9. Under such conditions, the concentration of silica, the dioxide form of silicon, was presumably higher in seawater than it is today.

The formation of the skeleton is a multifaceted process and will be explained in an exemplary way for Porifera. Even though these animals comprise the most simple body plan, their biomineral structure formation is already highly complex and by far not completely understood. Like in triploblasts, the diploblastic Porifera skeleton formation also has a pronounced effect on morphogenesis. As an example, if the animals are growing under unfavorable conditions that do not allow the formation of inorganic deposits (silica or calcium biominerals), the growth of the specimens is extremely suppressed.

Silica is the major constituent of sponge spicules in the classes Demospongiae and Hexactinellida. The spicules of these sponges are composed of hydrated, amorphous, noncrystalline silica. The secretion of spicules occurs in Demospongiae in specialized cells, the sclerocytes; there, silica is deposited around an organic filament. If the formation of siliceous spicules is inhibited, the sponge body collapses. The synthesis of spicules is a rapid process; the 100 μm long megasclere are formed within 40 h.

Inhibition studies revealed that skeletogenesis of siliceous spicules is enzyme-mediated, more particularly, by an Fe^{++}-dependent enzyme. Recent studies revealed that the dominant enzyme that catalyzes the formation of monomeric to polymeric silica is mediated by an enzyme

that belongs to the cathepsin subfamily and was termed *silicatein*.

The formation of siliceous spicules in sponges is genetically controlled; this process initiates the morphogenesis phase. Data demonstrated that at suitable concentrations, silicate induces genes, for example, those encoding collagen, silicatein, and myotrophin. A major step forward in elucidating the formation of the siliceous spicules on a molecular level was the finding that the ''axial organic filament'' of siliceous spicules is in reality an enzyme, silicatein, which mediates the apposition of amorphous silica and hence the formation of spicules.

The skeletal framework of the sponges is highly ordered. In two examples, the demosponge *Lubomirskia baicalensis* (Fig. 7a) and the hexactinellid *Euplectella aspergillum* (Fig. 7b), it can strikingly be seen that the growth of the sponges proceeds in a radiate accretive manner, meaning that growth zones, which are highly ordered are delimited by growth lines. These growth centers are constructed by an ordered arrangement of the spicules within the body. Most siliceous sponges are composed of larger megascleres, >10 μm long, and smaller microscleres (<10 μm). Some microscleres have a bizarre shape (Fig. 7c), while the megascleres usually have a long central rod with ends that in some cases are decorated with spines. Interestingly, the spicules (Fig. 7d) have the enzyme silicatein both in the central canal and also around the outer concentric silica layers. The central core rod of the spicule is synthesized first by the silicatein fiber, which exists in the central hole around which a 1 to 3 μm thick siliceous hollow fiber is formed. This layer becomes surrounded by an organic silicatein layer, which synthesizes the second siliceous layer and so on. This process of growth is very reminiscent of the process of bone formation.

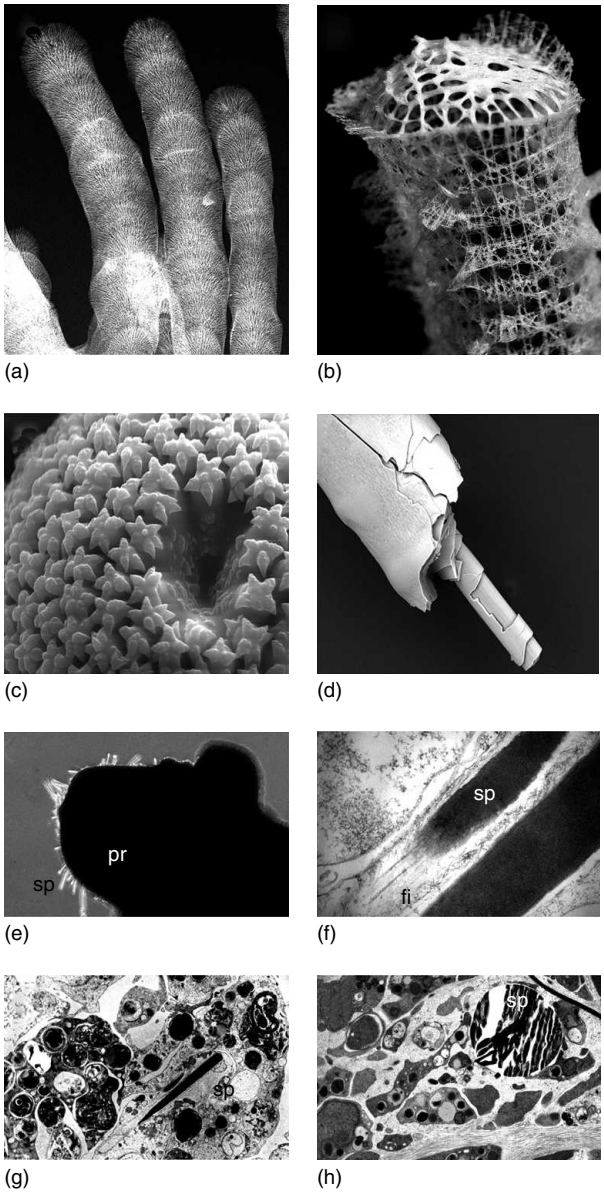
By applying the *in vivo* cell culture technique, the primmorphs, (Fig. 7e) the dynamics and cell biology of spicule formation could be studied. These experiments revealed that the spicules are formed extracellularly in close association with fibrils (Fig. 7(f,g)). Cross sections through a young spicule within cells from primmorphs show that the amorphous silica of the spicule is initially not very compact (Fig. 7h).

At present, no experimental data are available which could explain the species-specific form and shape of the spicules; it had been suggested that their polarity is the result of homeobox genes.

Fig. 7 The skeletal framework of the sponges is highly ordered. Radiate accretive growth pattern seen in the skeletal arrangement of the spicules from the freshwater demosponge *Lubomirskia baicalensis* (a) [x1] and the marine hexactinellid *Euplectella aspergillum* [x0.5] (b); the zones that are uniformly constructed are dissected by growth lines. (c) A microsclere from *Geodia cydonium*; x10 000. (d) Scanning electron microscopic analysis of basal spicules from *Hyalonema sieboldi* showing the concentric layers of silica layers by which they are built. The center of the spicule is composed of an organic filament, which comprises of the silica-forming enzyme silicatein and forms the first hollow fiber. Around the first fiber structure, silicatein is deposited again and forms the second concentric layer; x10. (e) A primmorph (pr), the cell culture spheroid from *S. domuncula*, has the capacity to synthesize spicules (sp); x20. Formation of spicules in primmorphs: (f) The newly formed spicule (sp) is closely associated with fibrils (fi); x5000. (g) Synthesis of a spicule in a sclerocyte within a primmorph; x1000. (h) Section through a primmorph, showing a sectioned young spicule; the amorphous silica of the spicule is not very compact.

3.3
Spicule Network in Sponges: A Unique Nervous System?

Sponges are devoid of a nervous system. In a recent study, the (potential) biological relevance of the spicules as optical fibers in sponges had been discussed from the view that they might substitute for a nerve system. For these studies, the hexactinellid sponge species *Hyalonema sieboldi* was selected; it is



characterized by extremely long spicules that form the stalk of these animals. It is remarkable that the internal siliceous layer(s) that surround the axial filament within the spicules display a higher flexibility than the layers that are deposited more outward. In order to analyze the optical properties of the stalk spicules as optical fibers, they were exposed at one end to white light. The first surprising result was that light was cut off below 615 nm and above 1310 nm. Within the visible part of the spectrum transmitted by the fibers, three less pronounced absorption maxima were determined. The percentage yield of transmission of the different wavelengths was again astonishing. It was found that almost 40 to 60% was determined at wavelengths around 900 nm (length of the spicules: 10 cm). From comprehensive studies of luminous genera, in organisms that are able to emit light through their bioluminescent systems, it is known that most pelagic deep-sea organisms emit light with maxima of emission spectra around 480 nm, while those that are terrestrial or live in freshwater produce light with longer wavelengths. Therefore, sponges were screened for a bioluminescent system, which generates light especially within the wavelength of 400 to 600 nm. This approach was successful; a gene was identified coding for a luciferase.

On the basis of these experimental findings, it appears to be justified to propose that sponges are provided with a so-far unrecognized photoreception system (Fig. 8A). Therefore, our group postulated that sponges coordinate their sensory reception systems not on the basis of a protein-controlled nervous network, but by their inorganic siliceous spicule system. Since they are provided with the genetic machinery to express luciferase enzymes, the optical fibers (spicules) might guide and convert the light, via a photoelectric reaction, into electric signals. From model systems, using supported bilayer lipid membranes, it is well established that some of them show photoelectric properties; likewise, photoelectric effects in plants are well known. Focusing on the sponge, in earlier elegant studies it has been demonstrated that tissue from the hexactinellid *Rhabdocalyptus dawsoni* could transmit electrical impulses more than 1 cm away from the place where the electric impulse was sent. The subsequent amplification system that translates the electric signals into the (nervous) transmission system, both in sponges and in other metazoan phyla are likely mediated by the same biological amplifiers, by receptors mediating the metabolism of the cells. While sponges are provided only with cells containing neuronal receptors, the neuronal cells of higher metazoans are connected by a nervous system. However, on the basis of the experimental data presented here, and the data from the literature, the system of spicules in sponges might substitute in these animals for the nervous systems of higher metazoans. This view is supported by *in situ* hybridization studies, which revealed that the spicules are surrounded by cells that selectively express not only the silica-forming silicatein (Fig. 8B(a)) but also a photomorphotropic protein (Fig. 8B(b)). These cells are characterized by their large diameter (>15μm).

It is concluded that sponges are able to react to physical stimuli, especially to light, with a coordinate reaction based probably on a system of glass fibers (spicules). It seems evident that this novel view of the photoresponsive

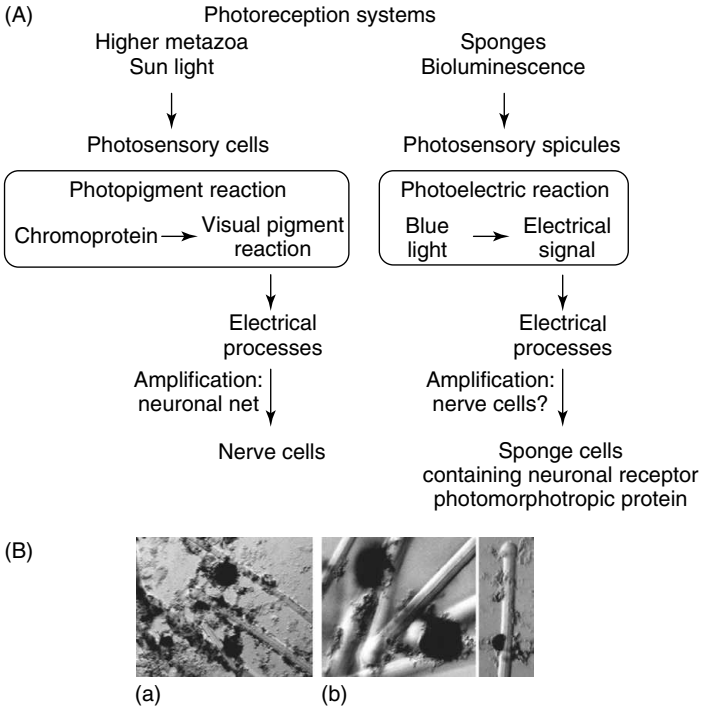


Fig. 8 Proposed photoreception system in sponges in comparison with that of higher metazoans. (A) In sponges, evidence is available that light is generated by bioluminescence (luciferase system), which is bundled by silica-based fibers. Within the blue light range, a photoelectric reaction takes place, converting the light into electric impulses. In contrast, the electrical impulses in higher Metazoa are generated by protein-based reactions. The amplification of the electric impulses in both systems occurs in nerve cells only, as in sponges, or in a neuronal net. (B) Large cells (>15 µm) surrounding the spicules which overexpress the *silicatein* gene [B(a)] and the gene expressing the photomorphotropic protein [B(b)].

properties of these animals, with the siliceous spicules as central elements provided with a photoelectric effect, will open new concepts in photoperception in animals.

4 Axis-pattern Formation

Pattern formation requires the defining of the main axes. As outlined, the diploblastic animals are characterized by one main body axis (apical/oscular–basal), the triploblasts have two axes (in addition to the anteroposterior one, the dorsal–ventral). Many signaling pathways are involved in those polarity-forming processes. Two large groups can be distinguished; first, pathways that originate from secreted signaling molecules, and second, those that are controlled by transcription factors. One example for each is given here.

4.1
Signaling Molecules: Wnt Pathway

The Wnt signaling pathway is a cell communication system that regulates cell-fate decisions, tissue polarity, and morphogenesis (Fig. 9). The Frizzled protein is the membrane receptor for the Wnt secreted glycoproteins. Through the canonical Wnt signaling pathway, the activated Frizzled binds to Disheveled (Dsh), which leads to the stabilization and accumulation of ß-catenin in the nucleus, where it activates the TCF/LEF transcription factor. Besides this canonical Wnt signaling pathway, two further related pathways have been identified: first, a signaling pathway downstream of Dsh, which includes the Rho and JNK cascade and was termed *noncanonical Wnt signaling pathway*; and second, the Wnt/calcium pathway that stimulates intracellular calcium release in a G protein–dependent manner. In vertebrates, the canonical Wnt signaling pathway is involved in axis specification, noncanonical Wnt signaling in the formation of cell polarity and convergent extension, and the Wnt/calcium pathway in tissue separation.

Recent studies demonstrated that genes encoding the Frizzled (Fz) receptor, as well as genes expressing proteins downstream of this receptor are present already in sponges. *In situ* hybridization analysis in adult *S. domuncula* specimens demonstrated Fz expression in the cortex region and in the epithelial layer of the aquiferous canals. Furthermore, Northern blot analysis revealed an upregulation of its levels of expression during the formation of sponge primmorphs. These findings suggest that a Wnt pathway involved in cell-fate determination and morphogenesis is already established in the phylogenetically oldest metazoans, the sponges.

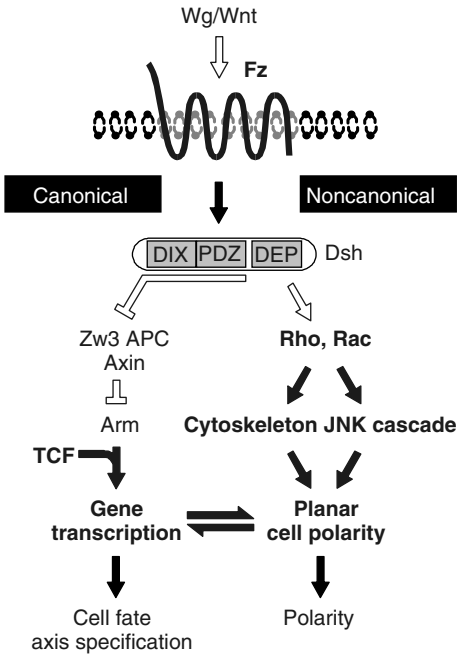

Fig. 9 Wnt signaling pathway. The extracellular Wingless (Wnt) ligand binds to the Frizzled receptor (Fz), which regulates cell-fate decisions through the Disheveled (Dsh) molecule that is composed of three functional domains (DIX, PDZ, DEP). From there two pathways lead either to the activation of the TCF/LEF transcription factor or to the JNK kinase cascade. The resulting selective gene expression causes a planar cell polarity. Those molecules that have already been identified in sponges are highlighted in bold.

4.2 Transcription Factors: T-box – Forkhead

During development, sets of genes, most of them transcription factors that are responsible for cell-fate and pattern determination, are expressed. Among them, T-box, Forkhead, and Homeobox gene families are mentioned, since they have been found to be extremely conserved on sequence and functional level in all metazoans.

Members of the T-box family, for example, Brachyury, are involved in the formation and differentiation of the third germ layer, the mesoderm, in triploblastic animals. They are expressed first at the end of the blastula stage in the region of the presumptive mesoderm, and later during gastrulation; the expression is restricted to the region of the notochord and the tail bud. In the diploblastic *Hydra*, *Brachyury* is expressed in the endothermal epithelial cells of the hypostome, which forms the apical part of the head of the polyp. On the basis of this observation, it has been proposed that *Brachyury* is involved in the formation of the first body axis, underscoring that *Brachyury* is crucial for the patterning of axes and germ layers in diploblasts as well as in triploblasts. Moreover, *Brachyury* is also important for the formation of the apical pole, the head. Recently, two T-box genes have been isolated from the sponge *S. domuncula*; a *Brachyury* gene and a homolog of the Tbx2-3-4-5 genes from chordates, which, in the latter taxa are involved in the formation of the limbs.

Since the larvae of *S. domuncula* cannot be routinely cultivated, it is – at present – not possible to conduct experiments with them. Therefore, studies had been restricted to adult animals and cultured sponge primmorphs, which comprise proliferating and differentiating cells. Interestingly, it could be demonstrated that the expression of the *Brachyury* gene is upregulated in differentiating sponge cells during formation of canal-like structures, suggesting that already in Porifera the primordial axis is genetically fixed.

This assumption was subsequently confirmed by the isolation and phylogenetic characterization of five members of the winged-helix/Forkhead gene family from the sponge *S. domuncula*. Forkhead proteins form a subfamily within the large group of helix–turn–helix proteins. They are responsible for a wide range of functions and key roles in early developmental processes, during organogenesis, and also for the function of the major organs and tissues in the adult animals. HNF3β, the founding member of this gene family, is responsible for the formation of terminal structures that develop into the gut.

The expression pattern of *Forkhead* and *T-box*/*Brachyury* genes during late blastulae and early gastrulae, supports the assumption that these two sets of genes are required for the morphogenetic movements occurring during processes identical or phylogenetically preceding gastrulation. Moreover, the overexpression of *Brachyury* is seen from Porifera and Coelenterata onwards to the triploblasts in distinct regions, usually adjacent to the organizers.

4.3 Organizers

Axis formation requires the concentration of cells at a distinct region, which displays the property to induce a complete body axis, even after transplantation; this region is termed *organizer*. In triploblastic animals, the organizer is involved both in dorsal-ventral and in anteroposterior patterning, for example, the Spemann organizer or the Hensen's node. In

diploblasts, like Coelenterata or Porifera, the organizer is closely connected to the circulation cavity.

4.3.1 Spemann Organizer

Spemann in 1936 was the first to describe the action of an organizer in amphibians by demonstrating that the dorsal lip of the amphibian blastopore to the ventral side of another embryo resulted in the development of a twinned embryo. The lip was able to induce the central nervous system, a dorsal mesoderm, and a secondary gut cavity. These results showed that in vertebrates the processes of cell differentiation progress through a series of sequential cell–cell interactions involving different cell affinities. Subsequently, organizer-specific genes were isolated, for example, *goosecoid*, *LIM homeobox protein*, and *Forkhead*. Microinjection studies revealed that mRNA, for example, of *goosecoid*, is able to induce a secondary axis. Furthermore, cells that had been injected with organizer-specific transcription factors are able to recruit adjacent cells for axis formation. In addition to these nuclear factors, a collection of genes encoding secreted factors were also identified, noggin, chordin, and follistatin being among these. Interestingly, these molecules act as antagonists for extracellularly present growth factors; hence, those organizer secreted molecules were termed according to the growth factors they antagonize. Among these is the Frzb-1 protein (Frizzled-related protein), which has the same binding affinity as the Frizzled receptor but lacks the transmembrane domain. Therefore, the soluble Frzb-1 protein binds to the Wnt signaling molecule, removes the ligand from the signaling pool and in consequence antagonizes Wnt signaling.

4.3.2 Hensen's Node

This node, found in birds, is a structure analogous to the Spemann organizer. During the progression of the avian embryo from the blastula to the gastrula, one major structure is formed, which is termed *primitive streak*. Within this streak, a depression or groove is formed that gives rise to the blastopore. At the anterior end of the primitive streak, a regional thickening of cells is found, which represents the Hensen's node. Cells from the node form the notochord. Transplantation studies also confirmed that the node could induce a new axis in avian embryos again supporting the high functional homology of the morphogenetic proteins; the same set of expressed genes as in the Spemann organizer was found in the Hensen's node.

4.3.3 Coelenterata

The hydrozoan polyps comprise a gastrovascular cavity that opens to the outside environment with a mouth/head. The mouth is set on an elevated hypostome, which comprises organizer activity. If this region is transplanted to the gastric region, a new head, together with tentacles and body axis, is formed. Molecular studies revealed that the organizer expresses the characteristic regulatory genes, coding for transcription factors, for example, LIM-class homeodomain protein or Brachyury.

4.3.4 Porifera

In sponges, the water enters the animals through many porocytes on their surface, the inhalant openings, into the canals formed by the endopinacoderm and is then passed to the choanocyte chambers from where the water is driven to the central atrium and finally pressed through the oscule out into the environment. Generally, the number of oscules is restricted and most species possess only one

major oscule. Several lines of morphological/cytological and molecular biological evidence indicate that the aquiferous canal system in sponges represents the organizational center of the sponges (Fig. 10a). During embryogenesis, amphiblastula or parenchymella larvae are formed. In their interior cavity, first choanocyte chambers are formed; these chambers are the central organ-like structure that directs and controls the water current. Subsequently, canals are formed which finally fuse with the outer pinacoderm layer. The 3D-cell culture experiments likewise revealed that an increase of the water current in the culture fluid results in canal formation, controlled by the homeodomain protein Iroquois.

In order to determine if the oscule, as the morphologically most prominent region in the sponge, also acts as an organizer-like region, ablation/transplantation studies were performed. In *S. domuncula*, the specimens comprise only one oscule (Fig. 10a); the histological section shows a large atrium in which the excurrent

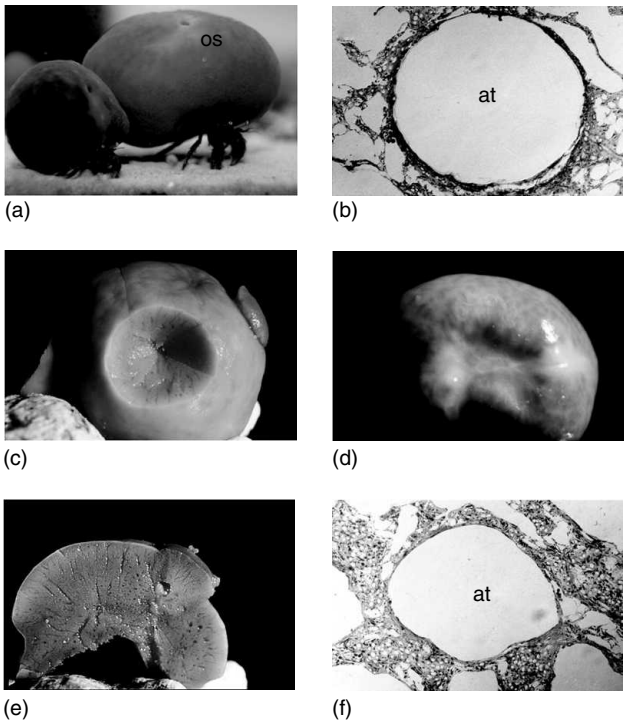

Fig. 10 Regeneration capacity of the oscule region in *S. domuncula*. (a) Each specimen contains one oscule (os); x1. (b) The histological section shows the atrium (at) below the oscule opening; x300. (c) If the oscule region is removed, the open surface (d) regenerates (for 14 days) by forming new epithelial layers, which, however, never show an oscule. (e) In contrast, if the oscule is removed from one place of the specimen and inserted into another region, the structure/atrium (at) of the oscule remains intact (14 days) (f); x300. (See color plate p. xxviii).

canals end and that opens into the oscule (Fig. 10b). The regeneration capacity of the oscule region is distinguished from the other regions of the body. After removal of the oscule (Fig. 10c), this area regenerates and is sealed only by an intact epithelium with a double pinacoderm layer, and not by the formation of a new oscule (Fig. 10d); also, at no other surface region is an oscule formed. However, if the oscule is excised and transplanted to another site (Fig. 10e), an intact oscule with an atrium is formed (Fig. 10f).

By applying a series of molecular/cell biological techniques, it could be demonstrated that the oscule region comprises the highest level of expressed genes, indicative of organizer regions. Among the genes that are overexpressed in the tissue surrounding the oscule are the LIM-homeodomain protein, Brachyury, Frizzled receptor, and also the secreted Frizzled-related proteins, noggin, or Iroquois. These data are strong arguments for the assumption that regionalized organizer centers are present from Porifera to the crown triploblastic species and are localized close to the openings of the body cavity.

4.4 Homeodomain Protein

In contrast to unicellular organisms, cells from metazoans also comprise genes for molecules that impart positional information in addition to genes encoding proteins for structural and narrow functional properties This property implies that cell movement within a specimen proceeds in a coordinate way to allow body plan formation. Hence, the cells have the ability to react to diverse temporally regulated interactions between shifting populations of cells and by that find their functional positions. These processes are driven by inductive proteins that are hierarchically expressed and that regulate cellular differentiation in order to connect the cells through complex form building cell movements.

In the two triploblastic model animals used for understanding the developmental gene network, *D. melanogaster* (Protostomia) and mouse (Deuterostomia) the anteroposterior/axial patterning of development is controlled by homeobox genes, coding for DNA-binding homeodomain transcription factors, which are even clustered in the genome. Most of the genes are expressed in a ''collinear'' way; the outstanding feature of this cluster is that genes at one end of the cluster are expressed and induce pattern formation at the anterior end of the embryo, while the genes at the other end of the cluster pattern the posterior of the embryo. Finally, the genes in the central region of the cluster pattern the middle of the embryo. This feature is termed *spatial colinearity*. In addition to the process of spatial colinearity, ''temporal colinearity'' exists, a process that implies that genes at one end of the cluster are activated first and genes expression is initiated progressively through the cluster until finally the genes at the opposite end are turned on. The building blocks of these clusters are represented by homeotic genes, comprising the homeobox. After the discovery that this homeobox is present in all of the clustered homeotic genes that code for sequence-specific DNA-binding domains, and the almost parallel discovery that the arrangement of the homologous genes is similar in insects and vertebrates, a comprehensive molecular comparison of the developmental processes in triploblasts became possible.

4.4.1 Insects – Drosophila melanogaster

The major difference between the mechanisms of expression of the homeobox genes in Protostomia and Deuterostomia is that the protostomian insects retain much of the segmental pattern of the body plan of a more simple organism. In *D. melanogaster*, the definite anteroposterior pattern is achieved in stages. First, genes of maternal origin are transcribed, followed by the sequential expression and function of the segmentation genes, which had been termed *gap* genes, *pair-rule* genes, and *segmental polarity* genes. On the basis of this sequential expression, a segmental periodicity is caused in the embryo along the anteroposterior axis; the identity of these individual segments is specified by homeotic selector genes (Fig. 11).

The basic modules of the segments in insect embryos are the ''parasegments'' from which the ''segments'' derive. The parasegments appear on the surface of the embryos after gastrulation. In *D. melanogaster*, 14 parasegments are delimited, which represent independent developmental units and acquire their own identity. The characteristics of the parasegments are that they are out of register with the final segments, which are seen in the late embryos and the adult specimens. Each segment is composed of a posterior region of one parasegment and an anterior region of the next one. In the head region of the adults, the segmental arrangement is lost. The gene clusters composed of homeobox genes, which delimit the parasegments are termed *pair-rule* genes. They are expressed in stripes; seven even-skipped pair-rule genes define the odd-numbered parasegments while seven others, for example, the *fushi tarazu*, define the even-numbered parasegments. The activity of the *pair-rule* genes is only temporary. During the process of cellularization of the blastoderm, the segment polarity genes are expressed. Among these is the transcription factor ''engrailed,'' which is expressed in the anterior region of every parasegment. In contrast to the *pair-rule* genes, the *engrailed* gene is active during the entire life of the fly and displays two functions; first, it delimits the boundary of cell lineage restriction and also acts as a selector gene, which helps to identify a region through its control of the activity of other genes. The anterior border of each parasegment has the important property to prevent movement of the cells of this parasegment into the adjacent parasegment. Such a cell lineage restriction seen at the anterior margin of the parasegment in insects or at the boundaries between the rhombomeres of the vertebrate hindbrain implies that the same common genetic control mechanism(s) act within a stripe of the anteroposterior oriented embryo. An area that is delimited by the restriction of cell lineages has been termed *compartment*. Within a compartment, genes such as *engrailed*, which are expressed in the anterior margin of the parasegments, establish a boundary of lineage restriction and prevent primordial cells and their descendants from one side of the boundary from crossing.

The segments of the late embryos and the adults derive from the parasegments. Each larval segment is composed of the posterior region of one parasegment and the anterior region of the next parasegment. Hence, in the segments the *engrailed* gene is now expressed in the posterior region. Segmentation has a well-defined anteroposterior pattern and can be morphologically seen on the ventral site of the abdomen. The anterior region of each segment comprises the denticles (outgrowth of the cuticle), while the posterior region is naked. Besides *engrailed* which together with *hedgehog* is expressed at the anterior

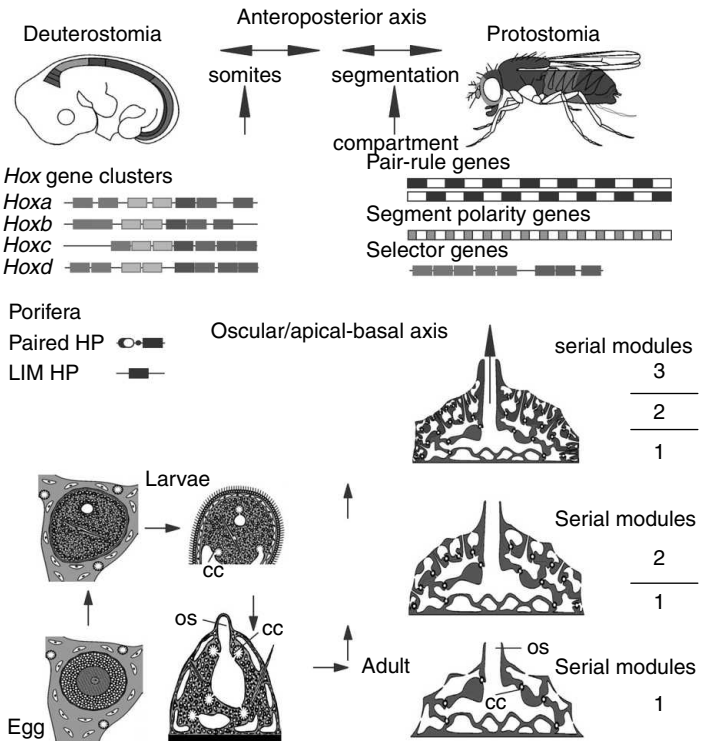

Fig. 11 Schematized view of the pattern formation in Metazoa. In the triploblasts, both the Deuterostomia, with the mouse as a model system, and the Protostomia, with the *Drosophila melanogaster* model, pattern formation is spatially and temporally controlled by homeobox gene clusters. In the mouse, several different clusters exist; their genes are positionally and combinatorially expressed along the anteroposterior axis. Colinearity exists between the order of *Hox* genes on the chromosome and the order by which the individual genes are expressed along this axis. In the insect, *Drosophila*, regular segmentation along the anteroposterior axis takes place. Prior to segment formation, parasegments develop. Sets of gene clusters (pair-rule genes) control parasegment formation; both genes defining odd-numbered parasegments and even-numbered parasegments are in action. Parasegment polarity is accomplished by the ''segment polarity'' genes. Subsequently, segments are formed from one anterior and one posterior region of a parasegment. Homeotic selector genes that help identify a particular region are present in a cluster and are grouped into an Antennapedia and a bithorax complex. In contrast to these triploblasts, the sessile diploblastic Porifera comprise an axis, which is usually defined by the location of the oscule (os). During embryogenesis, the fertilized egg develops into a larva, which comprises a cavity. During and after the settlement of the larvae, first choanocyte chambers (cc) are formed and the body cavity opens to the external milieu through an oscule. The growth of the adult proceeds along the oscule axis, apical/oscular–basal axis in a compartmental manner. It is proposed that the growth of sponges, occurs by serial modules, along the body axis; these processes are controlled by paired-class and LIM-class homeoproteins (HP), which are not arranged in a cluster on the chromosome. (See color plate p. xxx).

margin of each parasegment, additional genes are expressed at the posterior margin, for example, *wingless*. These polarity genes determine the segment patterning. It is interesting to note that *wingless* and *hedgehog* code for secreted signaling proteins that are not restricted to insects, but are also found in vertebrates where they are key players in pattern formation also.

Each segment has its own identity. As mentioned earlier, the same segment polarity gene is turned on in each segment. The specification of the identity of each segment is under the control of master regulator genes, termed *homeotic selector* genes. They control the expression of other genes throughout the development and are arranged into two gene complexes that share some homology with the *Hox* genes in vertebrates. In insects, two complexes are distinguished, the Antennapedia complex and the bithorax complex. Since all of these transcription factors contain a homeobox, they have also been collectively termed *HOM* genes. The genes of the Antennapedia complex encode transcription factors, which specify the anterior region, while the bithorax complex comprises the homeobox genes involved in the specification of the thorax. In the bithorax complex, three homeobox genes exist, *ultrabithorax* as well as *abdominal-A* and *-B*. The expression of these genes has already been seen in the parasegments; *ultrabithorax* is expressed in all parasegments from 5 to 14, while the expression of *abdominal-A* occurs in parasegments from 7 onwards, and *abdominal-B* from parasegments 10 onwards. Their combined/combinatorial activities define the character of each parasegment and are under the control of the pair-rule proteins, which are turned down in the initial phase of the development; subsequently, their correct expression is controlled by two groups of genes the *polycomb* and *trithorax* groups. The genes of the Antennapedia complex (*labial, proboscidea, deformed, Sex combs reduced, antennapedia*) are likewise spatially expressed and controlled in the anterior parasegments from anterior to posterior.

It is one characteristic of the bithorax and the Antennapedia complex that the order of the genes in the complex is the same as they are expressed along the anteroposterior axis during development. As an example, the *ultrabithorax*, which is located at the 3′ side of *abdominal-A* on the chromosome, is expressed more anteriorly and activated earlier than *abdominal-A*. This feature of temporal and spatial colinear expression of the genes within the insect *HOM* genes is highly conserved and also seen in vertebrates.

4.4.2 Vertebrates – Mouse

After gastrulation, the main axial structures of the vertebrate embryos (Deuterostomia) – somites, notochord, and neuronal tube – are formed. The regional organization and the anteroposterior axis formation start with the development of the somites from the most ventral region of the mesoderm at both sides of the embryo, while the notochord and the subsequent neurulation develop as a rod in the dorsal midline of the mesoderm. From the somites, the body and limb muscles derive and the cartilage is formed, which gives rise to the vertebrae, ribs, and dermis. The anteroposterior orientation of the mesoderm can be morphologically identified on the basis of the anatomical characteristics of the vertebrae, which depend on their locations along the axis.

The anteroposterior patterning is genetically controlled by clusters of homeobox genes (Fig. 11). Like in *Drosophila*, the

homeobox genes (*Hox*) specify the positional identity along the anteroposterior axis. *Hox* genes are known not only to control patterning of mesodermal structures along the anteroposterior axis but are also involved in the positional organization of other regions of the embryo, for example, the hindbrain. Vertebrates have four separate *Hox* gene clusters, which very likely arose by gene duplication. Again, like in insects, the vertebrate genes in the clusters are also expressed in a temporal and spatial order and reflect the arrangement on the chromosome. The best-studied model is the mouse. The *Hox* genes are first expressed in the anterior region in mesoderm cells at the early stage of gastrula. The pattern of expression of a given *Hox* gene is relatively sharp at the anterior border while it is less defined at the posterior borders. Most regions within the anteroposterior axis in the mouse embryo are characterized by a defined set of expressed *Hox* genes.

The positional identity of the somites is specified by the combinatorial expression of the genes of the Hox complexes along the anteroposterior axis. Again, the order of expression of the genes corresponds to their order on the chromosome. It should be stressed here that in vertebrates, retinoic acid can alter the positional "value" of a cell during development, especially during limb formation, and modulates the orientation of the anteroposterior axis.

A further class of Hox clusters has been identified in triploblasts, the paraHox cluster. It has been postulated that the paraHox cluster evolved from a putative Proto-Hox cluster. Also, these genes exhibit colinearity in neural tube and gut endoderm where they are associated with craniocaudal patterning. In mammals, the cluster consists of *Gsh1*, *Pdx1*, and *Cdx2*. The paraHox cluster also exhibits spatial and temporal colinearity; however, the temporal colinearity is inverted with respect to the pattern of the Hox cluster. In the paraHox cluster, the posterior gene *Cdx* is activated first, followed by *Xlox*, and then finally the anterior *Gsx* gene.

It should be stressed here that most of the homeobox genes present in Metazoa do not belong to the homeobox complex or are not involved in homeotic transformations.

4.4.3 Coelenterates–Cnidaria

In Cnidaria, both *Hox* and *paraHox* genes have been identified. In consequence, it was postulated that these two classes of clusters emerged by duplication from an ancestral minimal cluster of two to three *proto-Hox* genes within the Cnidaria. In *Hydra*, several *Hox/paraHox*-related genes, for example, *cnox-1*, *cnox-2*, or *cnox-3* have been identified and their expression was analyzed by *in situ* hybridization. In adult specimens, the three genes are expressed in the ectodermal layer, but are regionally different. These genes are not clustered; nevertheless, they display developmental functions, suggesting that clustering is not required for pattern formation.

More recently, a series of additional transcription factors have been identified in Cnidaria, which belong to the *Pax* gene family. These genes encode factors with multiple DNA-binding domains; they are defined by the presence of the paired box, which had been first identified in the Drosophila pair-rule gene *paired*, and encode a large DNA-binding domain. This domain is very similar to the homeodomain structure; some of these transcription factors contain a homeobox domain upstream of the paired box. Expression studies revealed that the cnidarian *Pax* gene is expressed in

transectodermal cells, very likely in areas where neurons differentiate.

Besides the *paired*-class homeobox genes, Antennapedia-class homeobox genes have also been identified, which are expressed in the head region and the apical pole. Until now, the LIM-class homeodomain proteins, known to be involved in the anterior organizer activity in chordates, have not been found in Cnidaria. These LIM-homeodomain proteins control cellular differentiation by activating transcription of cell type–specific genes.

4.4.4 Porifera

After the new view of the monophyletic origin of all metazoans, including Porifera, and the findings that both the immune system and the body plan comprise common basic elements in all animals, it was not too surprising that the ancestral homeobox genes are also present in sponges. The developmental processes resulting in the formation of a body axis require a head center; for example, in bilaterians, the Spemann's organizer. The genes that are involved in the establishment of the head organizer during embryogenesis have been grouped into three classes of *homeobox* genes, the *paired*-class, the *Antennapedia*-class, and the *LIM*-class genes.

In this area, rapid progress has been made in sponges in the last few years. A *paired*-class (*Pax-2/5/8*)-gene had been isolated from the freshwater sponge *Ephydatia fluviatilis*, which encodes a complete although substantially degenerated homeodomain. In *S. domuncula* a cDNA encoding an LIM/homeobox protein has been isolated, which comprises high sequence similarity to the related LIM-homeodomain proteins in other animals. The potential function of this protein in the sponge was elucidated in the primmorph model. If these 3D-cell aggregates were cultured on a homologous galectin matrix on which they form canal-like structures, morphogenetic processes are triggered, which also involve the LIM/homeobox protein/transcription factor.

A further putative homeobox gene, the *Iroquois*, was isolated from *S. domuncula*. The putative Iroquois transcription factor was found to be expressed in those cells that are adjacent to the canal system of this species. The finding that in sponges also the expression of the *Iroquois* gene is restricted to a specific tissue region, here the aquiferous system, adds a further piece to understanding the complexity of tissue organization in sponges. This finding underscores the fact that spatial and temporal expression of genes is one key process that establishes axes in Metazoa.

As mentioned earlier, the small hydrophobic molecule, retinoic acid, plays an important role in local signaling of homeodomain factor-mediated vertebrate development. As the first metazoan nuclear hormone receptor, the RXR had been identified in the phylogenetic oldest phylum Porifera. After identification, the role of the RXR was studied in the primmorph system. As in vertebrates or in Drosophila, retinoic acid is also formed in *S. domuncula* from ß-carotene via cleavage by the ß,ß-carotene-15,15′-dioxygenase to retinal and on further oxidization, to retinoic acid. Retinoic acid (9-*cis*-retinoic acid) binds to RXR resulting in a regulation of transcriptional activity of morphogenetic genes, including a homeobox gene also.

5 Origin of Metazoan Pattern Formation

The major difference in the genetic control of the body plan patterning between

diploblasts and triploblasts should be seen in the fact that only the triploblasts (both Protostomia and Deuterostomia) are composed of clusters of homeotic genes. In diploblasts, these clusters are missing and nonclustered *paired*-class (*Pax-2/5/8*)- and *LIM/homeodomain* genes control pattern formation. In triploblasts as well as in diploblasts, body plan formation starts by polarization of the embryo and subsequent development is followed in diploblasts only to the stage of serial module patterning, while in triploblasts the development to the adults includes both compartmental patterning and the subsequent segmental patterning (Fig. 11).

5.1 Serial Module Construction of the Body Plan in Diploblasts

Focusing on Porifera, after fertilization the zygote increases in size and develops flagellae. Depending on the taxa, morphologically slightly different types of larvae (amphiblastulae, parenchymellae, or coeloblastulae) are formed and released from the maternal body. During this phase the embryo polarizes, a process that is morphologically primarily obvious in the localization of the cilia and the formation of the body cavity (Fig. 11). Then gastrulation takes place driven by an asymmetric and tangentially arranged cleavage. The epithelia within the body cavity invaginate under formation of the choanocyte chambers. The embryos become sessile and the young sponge forms an oscule through which the body cavity opens to the external milieu; with this process, the young sponge forms an oscular/apical–basal axis.

The oscule region – as mentioned earlier – can be considered as an organizer, since there the characteristic vertebrate organizer genes are expressed. In addition, this region is provided with a regeneration capacity, which is distinguished from the rest of the animal. Especially the organizer-specific genes, *LIM-homeodomain, Brachyury, Frizzled receptor, noggin*, and *Iroquois*, are expressed along the aquiferous system and the oscule. This water canal system is the combined route for feeding, secretion, and gas exchange. Strong evidence has been collected in the last two years, which indicates that these ''organizer'' genes are expressed around the canals and the oscule and display morphogenetic activity as well.

Already morphological inspection shows that sponges grow in a radiate accretive pattern, regardless of whether they inhabit an environment with pronounced seasonal changes, for example, of the temperature (Lake Baikal; Fig. 7a), or a more stable milieu (Antarctic, or tropic regions; Fig. 7b). X-ray analysis of the skeleton of the Lake Baikal sponge *L. baicalensis* reveals that the architecture of the specimens comprises a highly ordered arrangement of the spicules within the body (Fig. 7a). *L. baicalensis* follows an organized growing pattern, reflecting a radiate accretive growth process. This pattern is maintained throughout the body of the animals and can be seen both in the growing parts of the specimens, the tips, and the basis. During growth, new layers/rings of new longitudinal spicule bundles are added at the tip of the branches. A similar highly regular arrangement of the spicule formation can also be seen in the hexactinellid *E. aspergillum* (Fig. 7b). The latter species shows a regular arrangement of the spicules, which form the lateral stabilization network that leaves holes for the water canal system. The apical end of the specimens, which harbors the oscule(s),

also shows a considerably ordered arrangement. By morphological inspection it has become obvious that specification of the different units of the body is absent; the growth zones look identical.

There is no doubt that this highly ordered growth process of the Porifera is genetically controlled. With the discovery that organizer-specific genes are present at the tips of the branches, around the oscules, together with the fact that growth along the oscular/apical–basal axis proceeds by a radiate accretive pattern, it is suggested that at the "growth lines," which are readily seen between the preceding and the succeeding growth layers, genes are expressed which form "serial modules," along the oscular/apical axis (Fig. 11). The serial modules should not be termed segments because this would imply that they are built by a more complex genetic network, as a system seen in insects.

The growth of the Coelenterata follows the pattern seen in Porifera. In *Hydra*, a continuous growth proceeds with organization center(s) localized around the mouth. In these animals, organizer-specific genes are highly expressed around the apical mouth region. Identical to sponges the coral growth pattern also follows the radiate accretive type. The apical/basal axis formation is modulated in these diploblasts by morphogens, which have two centers in Coelenterata, the foot and the mouth, while in sponges apparently only one center exists, which is found around the oscule.

5.2 Compartmental/Segmental Construction of the Body Plan in Triploblasts

Both in Deuterostomia (e.g. vertebrates) and in Protostomia (insects) development starts by polarization of the fertilized egg, a process that is driven by differential gene expression. While in vertebrates axis formation is determined by a signaling center, the Nieuwkoop center during the initial cleavages, and the Spemann organizer in the late blastula, in insects, body axis is set up by asymmetrical expression of the maternal genes.

5.2.1 Protostomia (Example, Insects)

A series of maternal genes are locally differently expressed in the egg and establish the anteroposterior axis. By spatial distribution of the mRNAs and, subsequently, of the resulting proteins, a regionalization within the egg is established. Among these genes is the *bicoid*, which is expressed at the anterior end of the egg. The bicoid protein acts as a transcription factor and as a morphogen and by doing so switches on zygotic genes at different threshold concentrations; thus, it initiates a new pattern within the zygote along the anteroposterior axis. Other genes, for example, *nanos*, polarizing the embryo from the posterior end act like a morphogen, while *hunchback* is more uniformly distributed within the egg. Hence, the anteroposterior axis of the egg is determined by several oppositely directed gradients. Besides the anteroposterior axis, the dorsal–ventral axis is determined in the egg through a later set of oocyte–follicle cell interactions. The oocyte-surrounding follicle cells specify the ventral side of the oocyte by deposition of maternal proteins.

After fertilization, four main classes of zygotic genes are activated along the anteroposterior axis; these are the *gap* genes, the *pair-rule* gene clusters, the *segment polarity* genes and the *selector homeotic* gene cluster. The *gap* genes, the first zygotic genes to be expressed, are also transcription factors. Their expression is initiated

by the bicoid gradient in the syncytial embryo; resulting in a coordinated expression of the *gap* genes along the anteroposterior axis in the following order: *hunchback*, *giant*, *Krüppel*, and *knirps*. The perfect regular segmentation of the insect larva seen at its cuticle starts with the expression of the *pair-rule* gene clusters, which delimit the parasegments. During this process, the blastoderm of the larva is cellularized. The boundaries of these periodic parasegment patterns are fixed by the segment polarity proteins, for example, engrail, which act on cellular levels and cause lineage restriction are also termed *Compartmentalization*. The ''segment polarity'' proteins stabilize the position not only of the parasegments but also of the segments. Then, the identity of the segments, based on the arrangement of the parasegments, is conferred by the selector/homeotic genes. The spatial expression pattern of the two clusters, the Antennapedia and the bithorax complex, is determined by the preceding expression of the *gap* genes and *pair-rule* genes.

5.2.2 **Deuterostomia (e.g. Vertebrates)**

In contrast to the initial phases of the development seen in insects, the patterning of the vertebrate body plan occurs always on the cellular level. Hence, intercellular signaling molecules are key players that interact with cell surface receptors and in turn induce intracellular signal transduction pathways; examples are the fibroblast growth factor, hedgehog, Wnt proteins, or ephrins. As in insects, in vertebrates also the eggs comprise a distinct polarity (animal pole – vegetal pole), which influences the cleavage pattern. The site at which the sperm interacts with the egg determines the dorsal–ventral polarity of the embryo. The following movement of the cytoplasm/yolk material is the first important developmental process, termed *cortical rotation*. In turn, a signaling center becomes localized in the embryo, which is termed *Nieuwkoop* center; it determines the dorsal side.

The Nieuwkoop center has the potential to induce a second embryo at another site. Its molecular nature is that it consists initially of a uniform low level of transforming growth factor-ß (TGF-ß) signal expressed all over the embryo. Acting alone, TGF-ß induces the formation of premesoderm and generates a BMP signal, which causes the transformation to the mesoderm. The major role of the Nieuwkoop center is the specification of a further dorsal signaling center, the Spemann organizer. The latter center is located in the immediate neighborhood of the Nieuwkoop center at the late blastula/early gastrula. The anteroposterior axis is the result of the action of this Spemann organizer (in vertebrates), or the Hensen's node in chick. Both are localized at the dorsal lip of the blastopore. The centers mediate their morphogenetic function through their transcription factors, for example, Brachyury and LIM protein, and through secreted proteins, for example, noggin, all of which are molecules that are highly conserved from Porifera to vertebrates.

As a result of the morphogenetic activity displayed by molecules originating from the Spemann organizer, the embryo finishes gastrulation and establishes the main axial structures, the somites (originating from the mesoderm), the notochord (mesoderm), and the neural tube (ectoderm). Interestingly enough, the formation of the somites and the notochord is under the control of the paired-type homeobox gene family *Pax*, again molecules conserved from Porifera to Chordata. The expression of *Pax* is subsequently modulated by BMP as well as by Wnt family

proteins so that the somites confine muscle precursors. This process could be termed *Compartmentalization*. Finally, the positional identity of the somites along the anteroposterior axis is specified by the sequential expression of the *Hox* gene cluster. This specification is reflected by the differences seen in the vertebrae along the anteroposterior axis. Hence, the vertebrate *Hox* gene clusters parallel the function of the insect homeotic selector gene clusters and follow a ''somite'' pattern. The transcription factors that are expressed in a temporal and spatial defined order are also arranged in the same order on the chromosome. Again – like in insects – the anterior border of the expression is more sharply defined than the posterior one. Several *Hox* gene clusters are expressed in vertebrates; all of them are involved in the specification of the regional identity.

6 General Principles in Metazoan Pattern Formation

The genetic programs that control development and body plan formation of multicellular organisms, plants, and animals, have been shaped during evolution. In consequence, such gene networks that control development also provide information about the evolution of these organisms. During development, distinct cell types are generated in distinct spatial and morphological domains, which establish organized structures and a functional organism. After fertilization of an egg, a genetic program controls cleavage divisions, resulting in a rapid increase of cells during the different stages of embryogenesis, a phase that is usually not characterized by an increase in cell mass. In these phases, pattern formation starts a process that organizes the cells of different affinities and activities in a spatial and temporal pattern/way.

Setting up the body axis during pattern formation is different between animals and plants; in plants, cell migration and tissue movement are absent and also distinct differences in embryogenesis exist with the lack of gastrulation as an example. In plants, the ''set aside'' of undifferentiated cells in the meristems in shoot and root tips is a dominant principle to allow and maintain continuous cell division at each axis. In animals, developmental mechanisms involve asymmetric cell division, pattern formation, establishment of the form and growth. Until sequence data became increasingly available, only a few model organisms had been studied to elucidate the basic principles in developmental biology of animals. These were primarily the protostomians *D. melanogaster* and *C. elegans* and the deuterostomians, for example, mouse and frog. At present, we have surpassed the threshold for a comprehensive view in body-plan formation in Metazoa, including axial pattern formation, which will also contribute to a solution in completing the hypothesis in developmental biology, for example, in segmentation/somite formation. Until 10 years ago, it was not clear whether all metazoan phyla, including the Porifera, originated from one common ancestor and hence are monophyletic, or, that multicellularity in animals occurred more than once. In 1994, sequence data clearly showed that the cell–cell and cell–matrix adhesion molecules of similar structure and function are present in all animal phyla from Porifera to the crown triploblastic phyla, a view that resulted in the formulation of the first hypothetical metazoan ancestor, the Urmetazoa.

In parallel with the elucidation that in all metazoans the characteristic adhesion molecules are functional, it became increasingly obvious that also individuality of a metazoan specimen, including its immune system, is based on conserved molecules and signal transduction pathways. Genes and their functional proteins, which control cell behavior and cell fate were identified, also including the process of apoptosis, which is required for the elimination of unwanted cells that remain at a later differentiation stage. Inductive interaction between cells is one major characteristic in development. The underlying signals are either secreted diffusible molecules, which interact with cell surface receptors and elicit there a new gene expression program, or signals that pass from one cell to the other via junctions. The response of a given cell to inductive signals is strongly dependent on its actual state.

During embryogenesis, pattern formation requires a spatial and temporal gene expression resulting in the formation of one or several axes. While diploblasts, for example, Porifera and Coelenterata, have only two epithelial layers, triploblasts have three germ layers; furthermore, diploblasts are provided only with one axis (apical/oscular–basal), while triploblasts/bilaterians are provided with at least two (anteroposterior and dorsal–ventral). Axis formation requires a polarized organization center. In Porifera, it is the oscular region that lays down the body axis, and in Coelenterata it is the mouth region. Common to these centers in the diploblasts, and the Spemann organizer and Nieuwkoop center, existing in the triploblasts/Deuterostomia, is their repertoire on expressed genes, for example, *T-box* family and *Brachyury* or *noggin*. It is noteworthy that these molecules are conserved from Porifera to the triploblastic crown species. In Protostomia (insects), the axis formation starts with the polarized expression of the maternal gene in the egg.

Pattern formation in diploblasts and triploblasts is also strikingly initiated by homeobox genes, for example, *paired*-class and *LIM*-class ones. Again, these genes have been isolated and (partially) functionally analyzed from Porifera to triploblasts. However, with respect to these genes, a characteristic difference exists between the arrangement of the sponge and *Cnidaria/Hydra* gene on the chromosome and those in triploblasts. In insects and in vertebrates, the morphogenetic homeobox genes are arranged in clusters. In insects, the *pair-rule* genes and the homeotic selector genes are clustered on the chromosomes, and likewise in vertebrates the four *Hox* gene complexes are arranged and expressed in a colinear way. Since the body plan/axis formation in diploblasts is established in the absence of homeobox gene clustering, it has been suggested that clustering of the homeobox genes is not a prerequisite for axis formation. As one consequence of the absence of homeobox gene clusters, the body axis in diploblasts is established in a compartmental construction, while in triploblasts, compartmental arrangement of the tissue stripes is the basis for a segmental/somital construction of the body plan.

In conclusion, this survey provides a basis for a unifying concept of pattern formation in all metazoans, which is based on genes expressing soluble morphogens that interact with their corresponding receptors and morphogenetically active transcription factors, including homeodomain proteins.

Glycolipid
A sphingolipid that contains a head group consisting of simple or complex glycans.

Raft
A membrane microdomain enriched in sphingolipids and cholesterol.

Sphingolipid Storage Diseases
A class of inherited metabolic disorders caused by the defective lysosomal degradation of sphingolipids or glycosphingolipids.

Sphingosine-1-phosphate
A sphingolipid first and second messenger that stimulates growth and suppresses apoptosis.

Sphingolipids are ubiquitous components of cell membranes, and are found in plants, animals, and fungi, as well as in some unicellular organisms and prokaryotes. Sphingolipids consist of a sphingoid long-chain base to which a fatty acid is attached at carbon 2, and a variety of polar and nonpolar head groups at C-1; glycosphingolipids are sphingolipids containing one or more sugar moieties in their head groups. Metabolic pathways have been determined for most sphingolipids, but little is known about how these pathways are regulated. Recent interest in sphingolipids and glycosphingolipids has focused largely on their roles in signaling events, with ceramide and sphingosine-1-phosphate the focus of particular attention. Sphingolipids also play vital roles in the formation and stability of membrane microdomains (rafts), and complex glycosphingolipids play roles in recognition. These lipids are also involved in disease pathology, and the pathways of sphingolipid metabolism, as well as the lipids themselves, have been implicated as possible therapeutic targets and agents.

1 Introduction

Biological membranes contain three major classes of lipids, namely, glycerolipids such as phosphatidylcholine and phosphatidylinositol, sterols such as cholesterol and ergosterol, and sphingolipids (SLs) such as sphingomyelin and gangliosides. Until recently it was believed that SLs were no more than structural components of biological membranes having no regulatory roles, but studies initiated in the mid-1980s have demonstrated that SL biology is much more complicated than once thought. It is now known that SLs act as important signaling molecules in an analogous fashion to the better-described signaling functions of glycerolipids such as phosphatidylinositol and its derivates. These findings have generated tremendous excitement and renewed interest in SLs, and

in the complex glycosylated SLs, the glycosphingolipids (GSLs), which is reflected in the increased number of publications on this lipid class. For instance, sphingosine-1-phosphate was virtually unheard of until the early 1990s, and in 1996, the time of publication of the first edition of the ''Encyclopedia of Molecular Cell Biology and Molecular Medicine,'' only 35 citations to sphingosine-1-phosphate can be found in Medline; in striking contrast, more than 230 citations to this important lipid second messenger were found in 2003 alone. This is typical of the renewed interest in all SLs, including ceramide, sphingomyelin, and of no less importance, the GSLs. Thus, the last 20 years have seen an explosion of interest in this field, and the goal of this chapter is to briefly summarize progress and our current state of knowledge of SL and GSL biology. As J.L.W. Thudichum, the discoverer of SLs, stated in his treatise on the chemical constitution of the brain, first published in 1884, SLs are indeed of fundamental importance. However, as reflected in the name chosen for these lipids (inspired by the Sphinx of Greek mythology, whose raison d'étre was enigmatic, and still is), many questions remain unresolved concerning SL and GSL biology. Accordingly, although perhaps not quite as enigmatic as once thought, challenges in this field still abound.

2 Structures of Sphingolipids and Glycolipids

As is the case for all membrane lipids, SLs are amphipathic molecules having both hydrophobic and hydrophilic regions. However, unlike the glycerolipids, in which two fatty acids are esterified to the primary and secondary hydroxyl groups of glycerol, SLs contain only one fatty acid (although up to 20 different species of fatty acid varying in chain length, degree of saturation, and degree of hydroxylation can be attached to the sphingoid long-chain base), which is attached via an amide bond to a sphingoid long-chain base, normally sphingosine (*trans*-D-erythro-2-amino-4-actadecene-1,3-diol), sphinganine, or phytosphingosine (Fig. 1). The simplest SL, ceramide, has a minimal hydrophilic region comprising two OH-groups, whereas complex SLs contain a hydrophilic moiety such as phosphate in the case of ceramide-1-phosphate, phosphorylcholine in the case of sphingomyelin (SM), and sugar residues in GSLs. At least 500 different carbohydrate structures have been described in GSLs. Both neutral and acidic GSLs exist, and particular variety is found in the acidic GSLs, the gangliosides, which are defined as GSLs containing one or more sialic acid residues, with sialic acid being a generic term for *N*-acetyl- or *N*-glycolyl-neuraminic acid. Gangliosides can be divided into at least eight different classes depending on the type of sugars linked to ceramide; a selection of typical GSL structures is shown in Table 1. The number of possible individual SL and GSL structures, varying in sphingoid base, fatty acid, and hydrophilic head group, is therefore huge, but little or nothing is known at present about how this enormous complexity is generated and maintained, or about the possible specific functions of individual SLs and GSLs.

3 Metabolism and Intracellular Transport of Sphingolipids and Glycolipids

The biochemical pathways of SL synthesis and degradation are well documented, and

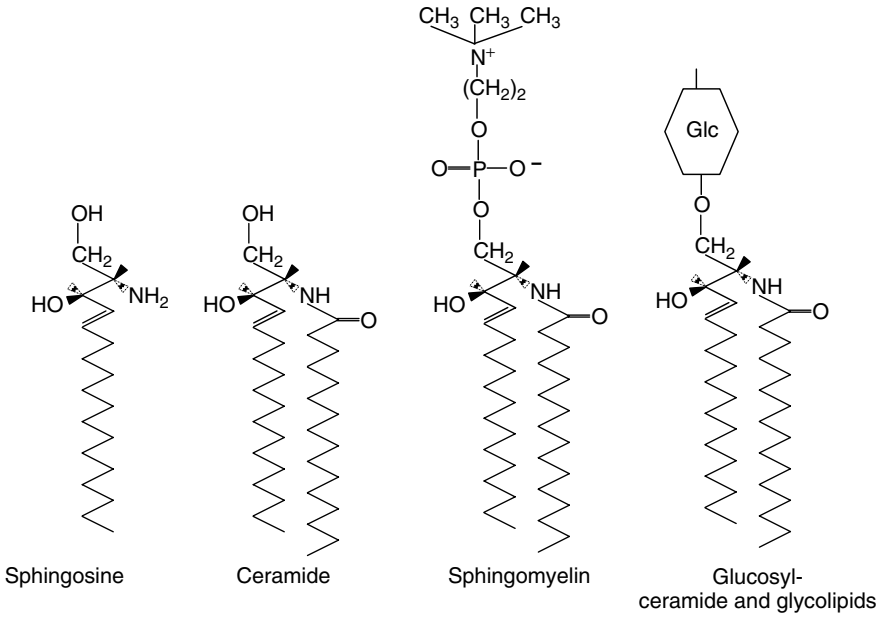

Fig. 1 The structure of simple SLs. For simplicity, only one kind of sphingoid base (sphingosine) is shown, to which one kind of fatty acid (palmitic acid) is attached. Sequential addition of other sugar residues to Glc(β1 $\rightarrow$ 1)Cer results in the formation of complex GSLs (Table 1 and Fig. 2).

most of the enzymes involved have been cloned, albeit some of them recently. SL synthesis begins with the condensation of palmitoyl CoA and serine-by-serine palmitoyl transferase to yield 3-ketosphinganine, from which sphinganine is produced by the action of 3-ketosphinganine reductase (Fig. 2). These two reactions, as well as the acylation of sphinganine to yield dihydroceramide, occur on the cytosolic leaflet of the endoplasmic reticulum, although the precise topology of each of these enzymes has not been fully elucidated. Sphinganine and sphingosine (the former produced mainly from the biosynthetic pathway and the latter via the degradative pathway) can be phosphorylated by sphingosine kinase to yield sphinganine-1-phosphate and sphingosine-1-phosphate, respectively.

The location of dihydroceramide reductase is not known, but most subsequent reactions, involving addition of head groups, occur in the Golgi apparatus. As the hydrophobic nature of ceramide prevents its spontaneous transfer through the cytosol, ceramide travels from the endoplasmic reticulum to the Golgi apparatus by facilitated vesicular and nonvesicular transport mechanisms. The latter involves a protein, CERT, which specifically extracts ceramide from membranes, is absolutely required for sphingomyelin synthesis, and contains a pleckstrin homology domain to allow its targeting to the Golgi apparatus. Interestingly, CERT does not appear to be involved in glucosylceramide formation, which occurs on the cytosolic leaflet of the Golgi apparatus, whereas addition of all other sugar moieties occurs on the

lumenal leaflet of the Golgi apparatus, as does the formation of sphingomyelin. Thus, CERT may be involved in regulating the synthesis of specific SLs by either its intrinsic specificity, or its interaction with dihydroceramide synthase, or with proteins involved in the transbilayer movement of SLs and GSLs in the Golgi apparatus. Subsequent formation of GSLs, including gangliosides, occurs by the stepwise addition of sugar residues by glycosyltransferases, which have defined substrate specificities but act on more than one GSL (Fig. 2). After their formation in the Golgi apparatus, GSLs and sphingomyelin move by vesicular transport to the plasma membrane, where they reside.

Although once believed to be restricted to the endomembrane system (i.e. those intracellular organelles connected by vesicular transport pathways), emerging evidence suggests that SLs and GSLs can also be found, albeit in small amounts, in other organelles such as the nucleus and the mitochondria. Thus, ganglioside GD3 relocates to mitochondria in response to some inducers of apoptosis, a neutral ceramidase has been found in mitochondria, and there is evidence for a sphingomyelin cycle in the nucleus. Little if anything is known about the dynamic interplay

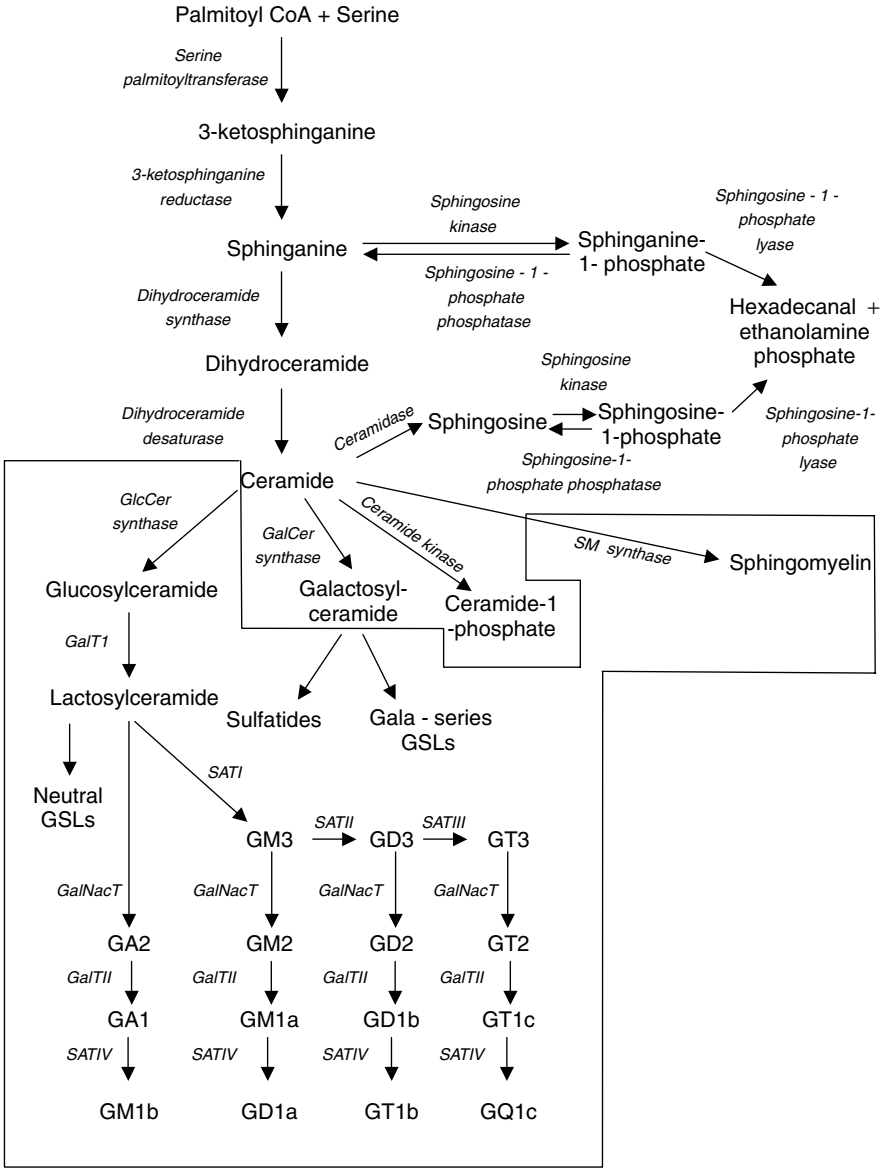

Fig. 2 The biosynthesis of SLs and GSLs. Not all metabolic pathways are shown. Enzymes are in italics. For GSL catabolism, see Table 2. Reactions within the box occur in the Golgi apparatus; all other reactions take place in the endoplasmic reticulum or cytosol.

between SL metabolism in the organelles of the endomembrane system and in other organelles not connected to them by classical vesicular transport pathways.

SLs and GSLs are internalized from the plasma membrane by vesicular transport involving both clathrin-mediated pathways and other pathways, including those

mediated by caveolin. Once internalized to endosomes, SLs and GSLs can either be recycled back to the plasma membrane or be further internalized to lysosomes, where their breakdown occurs by stepwise degradation, eventually yielding ceramide; SL and GSL degradation is defective in a number of inherited metabolic diseases, which will be discussed in more detail in Sect. 5. Ceramide is degraded by ceramidases to regenerate sphingoid bases. These bases act as substrates for the sphingosine kinases that form sphingosine-1-phosphate, which is subsequently degraded by sphingosine-1-phosphate lyase to yield hexadecanal and ethanolamine phosphate, providing a metabolic link between SLs and glycerolipids, and the only exit route of SL products from the SL metabolic pathway.

SL synthesis and degradation can be regulated at multiple levels, including through the control of enzyme expression, post-translational modification, and allosteric mechanisms. Some of these are cell-type specific, so as to control which SLs are synthesized during different stages of cell development, and some are in response to specific signals. Hence, although the basic blueprint of the biochemical pathways is well described, much still remains to be learned about modes of regulation of individual enzymes, and more importantly, about how flux through the metabolic pathways, and particularly at branch points where more than one enzyme can act on the same substrate, is regulated.

4 Functions of Sphingolipids and Glycolipids

Multiple functions have been ascribed to SLs and GSLs, and one of the challenges over the past couple of decades has been to make sense of the intracellular signaling functions newly ascribed to the simple SLs, mainly ceramide and sphingosine-1-phosphate, and of the functions ascribed to complex GSLs, mainly in events that occur at the cell surface. Elucidation of the exact function(s) that specific SLs and GSLs play in cell physiology, and how these functions are integrated and regulated, will represent a major achievement.

4.1 Signaling

Part of the reason for the recent explosion of interest in SL biology is the role that these lipids, particularly sphingosine, ceramide, sphingosine-1-phosphate, and ceramide-1-phosphate, have been shown to play in intracellular signaling. Ceramide and sphingosine-1-phosphate are the best-studied bioactive SLs and are produced for signaling pathways via the regulated activity of various enzymes. Thus, ceramide levels can be elevated in response to signals by activation of sphingomyelinases, or by *de novo* synthesis (Fig. 2). Sphingosine-1-phosphate is formed via the action of sphingosine kinase, but more than one sphingosine kinase exists and each enzyme is regulated by different means.

Ceramide and sphingosine-1-phosphate often exert opposite effects, with ceramide usually inhibiting proliferation and promoting apoptosis, and sphingosine-1-phosphate stimulating growth and suppressing apoptosis. Thus, many inducers of apoptosis or growth arrest activate one or more pathways of ceramide generation, and in many cases, there is evidence that endogenous ceramide mediates, at least in part, the apoptotic and growth arrest responses of these inducers (Fig. 3). Ceramide has been implicated in the actions of, for instance, tumor necrosis factor-α, and in the cytotoxic responses

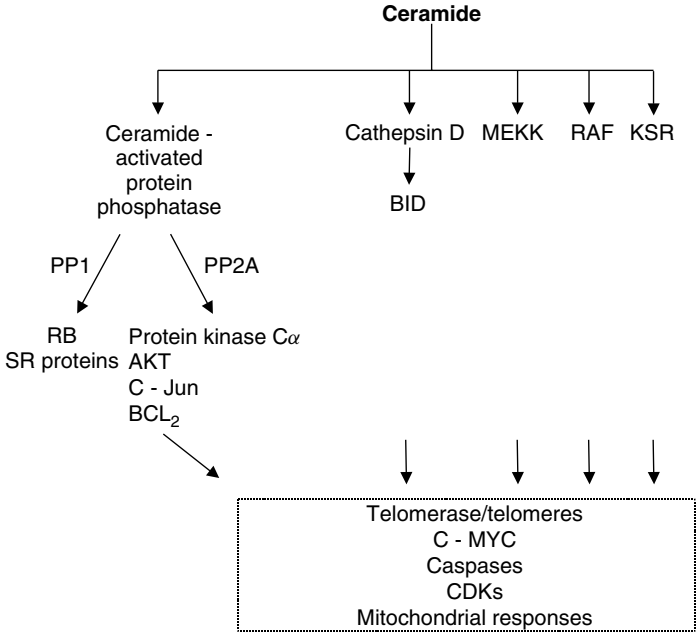

Fig. 3 Some proposed downstream targets of ceramide in signaling pathways. Ceramide generation, either via the *de novo* pathway or via the action of sphingomyelinases, results in a number of cellular responses, some of which are mediated by the signaling proteins and pathways shown in this scheme.

to amyloid ß-peptide, which suggests a role for this pathway in Alzheimer's disease and neurodegeneration. Conversely, many growth factors such as platelet-derived growth factor, as well as tumor necrosis factor-α, have been shown to induce sphingosine-1-phosphate formation, which in turn has been implicated in mediating viability and inflammatory responses. Much progress has been made in the past few years in determining the mechanisms of action of sphingosine (such as through the activation of pkh kinases in yeast), sphingosine-1-phosphate (primarily through the edg/sphingosine-1-phosphate receptors), and ceramide (through phosphatases and cathepsin D; Fig. 3), and such progress should allow the molecular determination of the specific mechanisms and roles of each individual bioactive SL.

Another huge impetus for study of SLs and GSLs was the observation that they are found in detergent-insoluble membrane lipid rafts. These microdomains have been implicated as both signaling platforms, and also as a means to traffic GSLs and certain proteins to specific membranes of polarized cells, such as epithelial cells and neurons. In terms of signaling platforms, it is now believed that acid-sphingomyelinase becomes exposed on the cell surface in response to stimulation via certain receptors, and the ceramide produced thereby modifies preexisting small rafts to fuse into larger signaling platforms and to trap activated receptor molecules in the platforms, thereby enhancing the

efficacy of signaling, and providing a functional and conceptual link between ceramide signaling and SL-enriched microdomains. This kind of mechanism may be particularly important in T-cell signaling. In terms of the role of rafts in sorting, considerable evidence exists that protein targeting can be mediated via rafts, but the fact that a protein is detergent-insoluble, together with SLs and GSLs, does not necessarily imply a functional interaction.

4.2 Functions of Complex Glycolipids

Early studies on complex GSLs were mainly devoted to attempting to understand their roles in the nervous system where GSLs, particularly gangliosides, are expressed at high levels. Gangliosides are expressed at different levels in different regions of the brain during development, suggesting functional roles for the gangliosides in brain development. For instance, during embryogenesis, and during the postnatal period, the hemato-series gangliosides, GM3, GD3, and 9-OAc-GD3, are highly expressed in the brain, but in adult tissue, these gangliosides are found at much lower amounts, so that the ganglioside composition of adult brain differs significantly from that of embryonic brain, inasmuch as adult brain expresses a much wider range of complex gangliosides, with GM1, GD1a, GD1b, and GT1b predominant. However, it was not until the cloning of the glycosyltransferases responsible for GSL synthesis, and subsequent availability of genetically engineered mice, that specific functions for specific gangliosides, or at least classes of gangliosides, began to emerge.

The essential nature of GSLs for sustaining life was shown in knock-out mice lacking glucosylceramide synthase, the first enzyme in the pathway of GSL biosynthesis (Fig. 2); these mice showed embryonic lethality, but whether this was caused by ceramide accumulation, or due to lack of complex GSLs, is unclear. Mice lacking the GM2/GD2 synthase gene (GalNacT, Fig. 2) contain high levels of GM3 and GD3, but no complex gangliosides. Surprisingly, these mice are viable and the nervous system is only mildly affected, although male fertility is severely disrupted due to aspermatogenesis. A number of other knock-out mice have been produced in the ganglioside biosynthetic pathway, and the overall consensus is that there is considerable functional redundancy between different ganglioside species, and that there may be considerable overlap in the roles of individual gangliosides.

One area in which individual gangliosides appear to have well-defined functions is their role as toxin receptors. In order for toxins to reach their intracellular targets, they bind to cell surface receptors, which are then internalized together with the toxins. Two toxins, namely, cholera toxin from *Vibrio cholera* and *Escherichia coli* heat-labile enterotoxin bind to ganglioside GM1, and Shiga toxin from *Shigella dysenteriae* binds to the neutral GSL, globotriaosylceramide (Gb3). The B-subunit of the toxins binds to their respective GSL receptors, and is internalized together with the A-subunit, which carries the catalytic domain. Lipid rafts have been implicated in the internalization mechanism, although there is some disagreement about the precise internalization itinerary undertaken by toxins attached to GSLs. What is clear is that the toxins are eventually targeted to the Golgi apparatus and then to the endoplasmic reticulum, where the A-subunit is released and initiates toxicity.

GSLs at the cell surface are also involved in recognition events that are

beneficial, unlike the toxic effects caused by toxin binding. Thus, a large body of data has shown roles for GSLs as antigens, as mediators of cell adhesion, and as modulators of signal transduction. The list of receptor functions of GSLs is extensive. For instance, GSLs mediate E-selectin-dependent rolling and tethering. α-Galactosylceramide acts as a ligand recognized by a special group of immune T cells, known as *invariant NKT cells*, and activates these cells to produce immunoregulatory cytokines, including interferon-γ and IL-4. 9-O-acetyl GD3, expressed in regions of cell migration and neurite outgrowth in the developing and adult nervous system, plays a role in neuronal motility. GSLs also act as T cell-stimulatory antigens by stimulating T cells expressing TCRαß or $\gamma\delta$ receptors. Together, these varied examples illustrate that the complex glycan structures of GSLs are involved in vital recognition events at the cell surface.

Finally, although this chapter focuses for the most part on SLs and GSLs in mammalian cells, these lipids are also important in lower organisms. Of particular note is the yeast, *Saccharomyces cerevisiae*, in which many of the enzymes of the initial steps in the biosynthetic pathway were first identified and cloned, and defined signaling functions of sphingosine-1-phosphate and ceramide, have been delineated. *Saccharomyces cerevisiae* does not contain complex GSLs, but rather contains inositolphosphorylceramides. Inositol-containing GSLs and glucosylceramide are found in plants and fungi, and galactosylceramide-based GSLs are found in fungi. As is the case in animal cells, SLs are involved in both intracellular processes and in cell-to-cell interactions in plants and fungi. These interactions may occur between cells of a multicellular organism or between cells of different species, as in host–pathogen interactions. In plants, recent studies have indicated that SLs are involved in signal transduction pathways, such as programmed cell death. Sphingenine-1-phosphate is involved in linking the plant hormone abscisic acid to stomatal pore regulation. In fungi, glucosylceramide has been linked to fruit-inducing activity. Inhibition of glucosylceramide synthesis can block morphological transitions such as budding and germ tube formation, and evidence is accumulating that GSLs play roles in fungal cell differentiation. One ongoing area of research is determining whether GSLs are involved in the interaction between mammals and pathogenic fungi.

5 Sphingolipids and Glycolipids in Disease

Much of the early work on SLs and GSLs was stimulated by their accumulation in a number of inherited metabolic diseases caused by defects in the lysosomal hydrolases responsible for their degradation (Table 2). For instance, Gaucher, Tay-Sachs, and Niemann Pick A and B diseases, in which glucosylceramide, ganglioside GM2, and sphingomyelin (SM) accumulate, respectively, are caused by the defective activity of the lysosomal enzymes glucocerebrosidase, β-hexosaminidase, and sphingomyelinase. A variety of symptoms are associated with GSL storage diseases, many of which involve central nervous system dysfunction, but the clinical presentation is very heterogeneous and progressive, with the rate of progression varying between disorders, and also within each disorder, and the diseases normally exist in infantile, juvenile, and adult forms. The most severe infantile forms present with acute brain

Tab. 2 SL and GSL storage diseases.

Disease	***Enzymatic defect***	***Major GSL storage material***
Gaucher	β-glucosidase, saposin C activator	Glucosylceramide
Sphingolipid activator deficiency	Sphingolipid activator protein	Glycolipids
GM1 gangliosidosis	β-Galactosidase	GM1
Tay Sachs	β-Hexosaminidase A	GM2
Sandhoff	β-Hexosaminidase A and B	GM2
GM2 activator deficiency	GM2 activator protein	GM2
Krabbe	β-Galactosidase	Galactosylceramide
Fabry	α-Galactosidase A	Globotriaosylceramide
Metachromatic leukodystrophy	Arylsulfatase A, saposin B activator	Sulfated glycolipids
Farber	Ceramidase	Ceramide
Niemann-Pick A & B	Sphingomyelinase	Sphingomyelin

involvement and patients die within the first years of life. In adult forms, symptoms develop more slowly and disability often arises mainly from peripheral symptoms. Juvenile forms are intermediate between infantile and adult forms. The reason for this heterogeneity is not known, but presumably depends on the level and nature of the accumulating GSL, and on the downstream biochemical and cellular pathways that are altered. However, despite years of study of the genetic and molecular basis of GSL storage disorders, little is known about the events that lead from lysosomal accumulation to the pathological manifestations described above. Presumably, study of these diseases would also yield important information about the normal physiological roles of SLs and GSLs.

In addition to the SL and GSL storage diseases, which result from defective degradation, SLs and GSLs have been implicated in many other diseases, notably cancer. In particular, crucial roles for ceramide and sphingosine-1-phosphate-mediated pathways have been identified in both cancer development and progression, with ceramide functioning as a tumor-suppressor lipid, inducing antiproliferative and apoptotic responses in various cancer cells, and sphingosine-1-phosphate acting as a tumor promotor. For example, an inverse correlation exists between the levels of ceramide and the degree of malignant progression and prognostic severity in patients with malignant astrocytomas. Similarly, the total content of ceramide is decreased in ovarian tumors compared with normal ovarian tissues. Ionizing radiation causes ceramide formation, and mice deficient in acid-sphingomyelinase lose the ability to accumulate ceramide and acquire resistance to radiation-induced apoptosis. In contrast, overexpression of sphingosine kinase results in cellular transformation in tissue culture and tumor formation. Sphingosine-1-phosphate has also been implicated in inflammatory pathways, which are themselves implicated in cancer pathogenesis. Complex GSLs might also be involved in cancer since they are shed from a number of

cancer cells and ganglioside depletion has been shown to reduce tumorigenicity. Together, these discoveries are paving the way for the advancement of anticancer therapies involving manipulation of SL signaling pathways and the formation of complex GSLs.

SLs and GSLs have also been implicated in the pathology of other diseases. Thus, anti-GSL antibodies are found in some peripheral neuropathies. Sulfatide has been implicated in thrombogenesis and hemostasis. Galactosylceramide and sulfatide are essential for node of Ranvier formation, involved in myelin formation. Other examples abound and based on all of these, SLs have also received attention as possible therapeutics. One of the most exciting is the possible use of ceramide-coated balloon catheters to target restenosis after angioplasty and/or intra-arterial stenting, which significantly reduces neointimal hyperplasia. Thus, SLs may eventually find their place as important therapeutic agents.

6 Perspectives

In this chapter, I have tried to share some of the recent excitement in SL and GSL research, and to show how these important lipids are impacting not only basic research but also modern medicine. Assuming that most structures of SLs and GSLs have now been discovered, and that the biochemical pathways have been delineated, the next generation of researchers in this field will no doubt devote most of its time to working out how these pathways are regulated, and whether the multiple different structures have defined functions in specific aspects of cell physiology and pathophysiology, or whether there is significant functional and structural redundancy.

Keywords

Angiogenesis
The formation of new blood vessels from preexisting blood vessels.

Human embryonic stem cells
Pluripotent embryonic stem (ES) cell lines derived from the inner cell mass of human blastocysts that have the developmental potential to form derivatives of all three embryonic germ layers even after prolonged culture.

Immunodeficient SCID/beige mouse
Severe combined immunodeficient (SCID) mice have a defect in the immune system that results in a lack of mature B and T cells, and thus are able to accept xenografts of human origin.

Teratoma
A nodule comprised of a wide variety of differentiated tissues and structures of normal human cells derived from injection of human embryonic stem cells into immunodeficient SCID/beige mouse.

Tumorigenesis
The process of tumor formation.

Tumor microenvironment
The complex network of intercellular interactions mediated by physical attachment, as in direct cell–cell or cell–stromal interactions, which has a significant effect on tumor physiologic characteristics such as growth pattern, vascular function, angiogenesis, and metastasis.

Vasculogenesis
The formation of new blood vessels that originate from endothelial cell precursors (angioblasts) during development.

There is currently no experimental system available wherein human cancer cells can be grown in the context of a mixed population of normal differentiated human cells for testing biological aspects of cancer cell growth (tumor cell invasion, angiogenesis), or response to anticancer therapies. Human embryonic stem cells when implanted into immunocompromised mice develop teratomas containing complex structures, comprising differentiated cell types representing the major germ-line derived lineages. We sought to determine whether human cancer cells would grow within such teratomas and display properties associated with malignancy, such as invasiveness and recruitment of blood vessels. Ovarian cancer cells (HEY), stably expressing an H2A-GFP fusion protein, which allows tracking of tumor cells, were injected into mature teratomas and developed into tumors. The growth, proliferative capacity, invasion, and induction of blood vessel formation were examined. We propose using this novel experimental platform to develop a preclinical model for investigating and manipulating the stromal response in tumor cell growth as an additional tool in cancer research.

1 Introduction

Human embryonic stem cells (hESC) have the potential to differentiate into complex structures, comprising differentiated cell types representing derivatives of all three major embryonic lineages. Embryoid bodies generated *in vitro* from human embryonic stem cells grown in suspension, and teratomas generated *in vivo* following injection into immunocompromised mice, contain a wide variety of differentiated tissues and structures comprised of normal human cells. Using these human differentiated cellular microenvironments, we have been able to demonstrate and investigate the growth and tumorigenic properties of a variety of human cancer cell types.

In recent years, there has been growing awareness that tumorigenesis properties are markedly affected by the surrounding tissue microenvironment at both primary and metastatic sites of tumor growth. Thus, it has been shown that tumor progression is associated with extensive remodeling of adjacent tissues to provide a supportive microenvironment for cancer cell proliferation, migration, invasion, and the formation of blood vessels required for supporting cancer growth. As an example, human prostate carcinoma-associated fibroblasts can promote tumorigenic transformation in initiated human prostate epithelial cells. In more recent studies, it was shown that the connective tissue stroma surrounding neoplastic breast tissue was induced into a state that promoted subsequent neoplastic growth in naïve breast epithelium. Also, in recent studies it was demonstrated that the genomic rearrangements characteristic of a given tumor type (e.g. lymphoma), could also be demonstrated in the adjacent endothelial cells of tumor-induced blood vessels. Appreciation of the important role stromal response plays in supporting tumor growth has led to the development of novel anticancer therapeutic agents targeted to disrupt stromal response factors, and thereby inhibit tumor growth. Particular attention has been directed at the development of anti-angiogenic molecules in particular, some of which have reached clinical trials.

Purely *in vitro* models using malignant cells in continuous culture, such as anchorage-independent growth and focus formation are not particularly amenable to the investigation of stromal interactions. It was the emergence of *in vivo* models using tumor xenograft growth in immunocompromised mice, which highlighted the importance of the stromal response in an experimental setting and have led to corresponding studies in the clinical setting. Accordingly, most preclinical studies of anticancer reagents have been conducted using injection of tumor cells as xenografts in immunocompromised mice. However, in the numerous published studies using this model, it has been the murine rather than the human stromal response, which has been the target of investigation or experimental therapeutic intervention.

Therefore, we utilized human embryonic stem cells in order to study the interactions of tumor cells with the surrounding heterogeneous microenvironment of differentiated human cell tissues and structures.

2 Methods

HEY ovarian cancer cells were injected into human embryonic stem cell–derived

teratomas that had been allowed to mature in SCID/beige mice (Fig. 1). The HEY ovarian cancer cells had been transfected so as to stably express a histone H_2A-GFP fusion protein, in order to facilitate the tracking of tumor cell growth and invasion. Following various periods of growth, immunohistochemical analysis of the mixed teratoma-tumor structures confirmed the feasibility of using this approach to examine human tumorigenesis properties in a human cellular microenvironment.

3 Results

The important findings using this novel approach included: (1) the development of a homogeneous mass of tumor cells with high proliferative capacity within the differentiated microenvironment of the teratoma; (2) the identification of invasion by tumor cells into the surrounding differentiated teratoma structures; and (3) the existence of blood vessels of human origin derived from hES differentiation. In this regard, we have demonstrated staining of such blood vessels by using antibodies to human-specific endothelial cell surface antigenic epitopes such as CD31 or CD34 in teratomas bearing tumors, and demonstrated the presence of blood vessels of hES origin, of various calibers and levels of maturity, growing adjacent to and within the tumor. Therefore, it will be important to rigorously quantitate differences in blood vessel development between teratomas without and with tumor growth using these immunoreagents. This immunostaining approach can be supplemented with quantitative molecular analysis of the known neovasculogenesis gene expression profile.

4 Discussion

This novel experimental approach using human stem cell technology has been extended to generate a novel experimental platform, in which a wide variety of human tumor cells can be grown in a preclinical setting in a tissue microenvironment consisting of differentiated human cells, for investigating cancer growth and anticancer therapy. We have examined and compared different multiple human tumor cell types with varying tumorigenesis properties, and correspondingly found differences in growth, invasion, and angiogenic responses using this new model.

Most significantly, we find that the heterogeneous hES derived microenvironment provides a supportive niche for tumor growth, which is not available to human tumors growing xenografts following direct injection in murine tissues. We postulated that this reflects the availability to the tumor of the variety of potential human supporting cells that the corresponding tumor would actually encounter in the clinical setting. This postulate is supported and strengthened by the finding of significant differences in the response to anticancer therapy in tumors growing in the human cell microenvironment of a teratoma in immunocompromised mice in comparison with the same tumors growing following direct injection into the hind limb muscle tissue of these mice. It remains to be seen whether such differences may be predictive of expected responses in clinical trials. It will also be possible to extend the applications of this model in a number of basic and applied directions. Among others these extensions include:

1. pharmacologic and/or genetic manipulation of either the tumor cells or the hES derived stromal cells, which could include stable transfection of the hES cells with constructs targeted to modify the levels of expression of key enzymes and growth factors involved in the stromal response to tumor growth and progression;
2. molecular analysis of hES derived surrounding stromal cells, isolated from the tumor growths; isolation of stromal cells of different histologic specificity

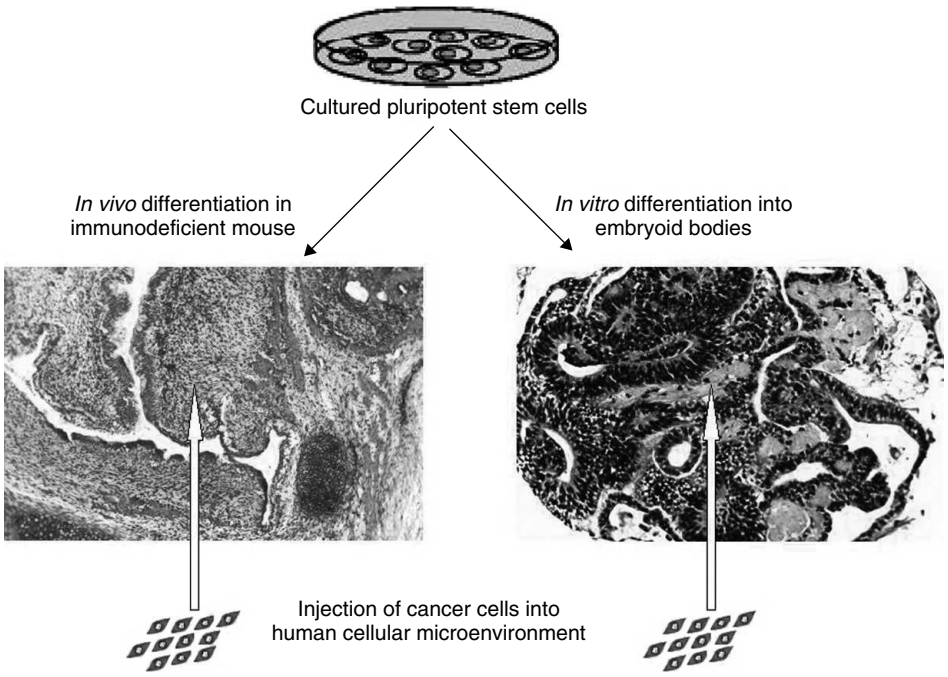

Fig. 2 An experimental platform for growing human tumor cells within a human cellular microenvironment derived from differentiation of human embryonic stem cells *in vitro* and *in vivo*. Copyright (2003) Discovery Medicine.

can be achieved by laser microdissection, and can be subjected to gene or protein expression analysis on relevant microchip arrays;
3. vital and functional monitoring of the tumor growth in response to therapeutic intervention, using modern imaging techniques applied to appropriately labeled or marked hES or tumor cells, including hybrid imaging with micro-PET/CT, or with luminescence or fluorescence detection.

It should be recognized that in the case of bulk teratomas and embryoid bodies, these structures are comprised of a mixture of cells, and lack the homogeneity or organization present in authentic human tissues. To this end, enrichment protocols and 3D polymer-based *in vitro* models have already been applied to human embryonic stem cell growth and will likely represent an important future step in optimizing the utility of the experimental platform that we have described. This model can be extended to the growth of tumor cells in a purely *in vitro* embryoid body configuration (Fig. 2).

5 Summary

In summary, we present and propose using a novel experimental platform consisting of human tumor cells growing within a human cellular microenvironment derived from human embryonic stem cells. The growth, invasion, and human neoangiogenic response observed indicate that these structures may serve as an important preclinical model for investigating and manipulating the stromal response in tumor cell growth, and thereby contribute to the progress of cancer research.

Keywords

Astrocytes
The most numerous glial cells in the CNS, astrocytes were traditionally defined by their star shaped morphology and believed to serve as support cells for neurons. It is now known that some astrocytes function as the neural stem cells in the adult brain.

Neural Stem Cells
Cells with the capacity for long-term proliferation that are capable of giving rise to progeny that differentiate into neurons, astrocytes, and oligodendrocytes. These cells are also able to self-renew, meaning they can divide to produce more stem cells.

Neurogenesis
The production of new neurons and the process by which they are born, migrate, and mature.

Radial Glia
Cells with a long basal process that extends from their cell body in the ventricular zone, through the parenchyma toward the brain surface. Classically, radial glia were viewed as immature glial cells that guide neuronal migration and function as scaffolding for brain development, but more recently have been determined to have neural stem cell properties.

Subgranular Zone
The region at the border between the granule cell layer and the hilus in the dentate gyrus of the hippocampus. This region is a germinal center and site of ongoing neurogenesis in the adult brain.

Subventricular Zone
The region of the brain lining the walls of the lateral ventricles. This region is a major germinal center and site of ongoing neurogenesis in the adult brain.

The adult brain continues generating new neurons. This discovery has dramatically changed our view of brain plasticity, and has also revealed previously unsuspected mechanisms of neuronal birth, migration, and replacement. In this chapter, we focus on the mechanism of neuronal birth and discuss recent data on how these new findings have changed concepts on the origin of neurons and glial cells in the adult, and developing central nervous system (CNS). Adult neurogenesis has been demonstrated in the forebrain of songbirds, and in the hippocampus and olfactory bulb (OB) of adult mammals, suggesting that neural stem cell are retained in the adult brain. These primary precursors have now been identified and shown to reside in specialized germinal niches. The composition and organization of these niches is discussed. Surprisingly, the primary precursor of new neurons in the adult brain has been found to be radial glial cells (birds) and astrocytes (mammals), glial cells

long considered to be part of a lineage separate from that of neurons. Work in the developing mammalian brain has shown that radial glia are not only precursors of astrocytes, but also of neurons, oligodendrocytes, and ependymal cells. Radial glia also serve as the precursors of adult neural stem cells. It is becoming increasingly clear that neural stem cells are contained within the lineage of neuroepithelial cells-radial glia-astrocytes. The identification of primary precursors in the developing and adult brain is fundamental to our understanding of neural development and adult neural replacement.

1 Introduction

For almost a century, the brain was conceived to differ significantly from other tissues that constantly self-renew. In these self-renewing tissues, primary progenitors or stem cells divide to regenerate different cell types, thus constantly replaying developmental programs in the adult for the purpose of tissue maintenance. For example, the bone marrow contains hematopoietic stem cells that divide to generate secondary progenitors that differentiate into different types of blood cells. The brain was considered different. It was thought that the important functions carried out by the brain required a stable network of neurons and that these fundamental cellular elements were not added or replaced in adult life, but only formed during a restricted period of embryonic and fetal life. It was believed that the mature brain was not able to support the birth, migration, and incorporation of new neurons, much less that these cells could then be integrated into functioning brain circuits. The progenitors and scaffolding required to support neuronal production and incorporation were thought to be present in the brain during just a limited period of development.

This traditional view has changed. Whereas many neurons in the brain are very long lived and indeed not replaced throughout life, new neurons are recruited into selective brain circuits probably in all vertebrate species, including humans. This conceptual shift raised fundamental questions about the mechanism by which new neurons are added to the adult brain. Investigations on the mechanism of adult neurogenesis revealed that neural stem cells were retained in the adult brain. The identification of these primary progenitors (stem cells) yielded an unexpected observation: these cells had the characteristics of astrocytes, a type of glial cell (the supportive cells found around neurons) previously thought to be fully differentiated and completely separate from the neuronal lineages. Here we will review how this field has evolved and how these discoveries, together with the recent identification of the stem cell in the developing brain, radically change the concepts in developmental neuroscience.

2 Adult Neurogenesis

Neurons do not divide. No one has ever observed a fully mature neuron undergo mitosis. Mitosis in the adult brain is rare and when observed it is associated with small cells and with

cells of glial character. It is for this reason that it was classically thought that while gliogenesis continues in the adult brain, neurogenesis stops soon after birth. However, determining what a cell that has undergone mitosis ultimately becomes is not a simple problem. [^{3}H]thymidine, an analog of thymidine that gets incorporated into DNA during S phase of the cell cycle, was instrumental to our understanding of the fate of dividing cells and to the discovery of adult neurogenesis. Early studies suggested that [^{3}H]thymidine was incorporated into neurons of adult brains after an electrolytic lesion. It was suggested that multiple neuronal types, including cortical pyramidal neurons, may be formed in the adult brain, and that some of these cells appear labeled with [^{3}H]thymidine as soon as one day after injection. Some of these early claims are not supported by more recent work, as we now know that it takes much longer for new neurons to form in the adult brain. More recent work, however, has confirmed that new neurons are indeed added to very specific circuits of the adult brain.

It was in an adult songbird, the canary, that neurogenesis was first demonstrated using, in addition to anatomical methods, ultrastructure and electrophysiology. Canaries display dramatic hormone-induced changes in brain regions associated with song production. It was this remarkable plasticity that led Goldman and Nottebohm to use [^{3}H]thymidine to determine whether new cells were added to song control nuclei. It was found that cells that incorporated [^{3}H]thymidine had the characteristic morphology of neurons at the light microscope. These cells also had the ultrastructure of neurons including synapses, they displayed action potentials and synaptic inputs typical of neurons, and some of the new neurons grew axons, which are only observed on nerve cells and not on glial cells. Neuronal recruitment in adult songbirds was first described in the song control nuclei, but was then shown to occur throughout most of the telencephalon. The new neurons are born in the ventricular zone (VZ) on the walls of the lateral ventricles. Just as in development, the precursors for the new neurons in the adult are not located at the site of differentiation, but in specialized germinal niches sometimes millimeters away from their site of final differentiation. Radial glia persist in the ventricular wall of adult birds, and the long processes of these cells guide the migration of young neurons in the brain from their site of birth to their ultimate destination where differentiation occurs. Little is known about the microenvironment in the avian VZ that supports the proliferation of neural precursors. The cell adhesion molecule N-Cadherin is concentrated in this region and has been suggested to play a role in maintaining the progenitor cells within the germinal niche. These studies firmly established that new neurons are added to adult birds.

New glial cells are also formed in the brain of adult canaries. However, in contrast to neurons, these cells seem to be derived from cells that divide locally within the brain parenchyma. This inference comes from the observation that at short survivals after [^{3}H]thymidine administration, cells of glial morphology appear labeled throughout the brain parenchyma. Furthermore, cells that migrate away from the VZ seem to give rise only to neurons. Evidence *in vitro*, however, suggests that both neurons and glia may be generated from dividing VZ cells in the brain of adult canaries. This may suggest that cells derived from the adult VZ in birds have the potential to form both neurons and glia,

but that the environment within the adult avian brain is only conducive to the differentiation of these new cells into neurons. Alternatively, separate precursors for neurons and glial cells may exist in the VZ of adults, but only the progeny of neuronal precursors migrates away from the VZ and differentiate.

Neurogenesis also continues in several regions of the central nervous system (CNS) of other vertebrate species including adult fish, lizards, and amphibians. The body and brain of most poikilotherm vertebrates continues to grow throughout life. Unlike mammals or birds in which neurogenesis is thought of as a process of cell replacement, in poikilotherms it has been suggested that neurogenesis is associated with growth of the body. For example, the retina of adult fish and frog keeps growing and this growth results, at least in part, from the addition of new neurons, including ganglion cells. Neurogenesis in adult lizards, however, appears to also have a role in regeneration. The medial cortex in lizards, a region equivalent to part of the hippocampal formation in mammals, thought to be important for spatial and olfactory learning, receives many new neurons in adults. Most interestingly, following a neurotoxic lesion that destroys most of the neurons of the medial cortex in adult lizards, rapid regeneration ensues, resulting in remarkable histological restoration. The regions in the VZ of adult lizards that give rise to the new neurons are well defined, and this should allow for the identification of the proliferative neuronal precursors that make these regenerative processes possible.

In mammals, the study of adult neurogenesis has been highly contentious. After years of debate over the identity of [^{3}H]thymidine labeled cells and whether it occurs at all in adult primates, it has now been clearly established that neurogenesis occurs in two regions of the adult mammalian forebrain: the olfactory bulb (OB) in the anterior telencephalon and the dentate gyrus (DG) of the hippocampus. Neurons destined for the OB are born in a specialized germinal region called the *subventricular zone* (SVZ). The SVZ is on the walls of the lateral ventricles caudal to the olfactory bulb. New neurons destined for the OB have to migrate a long distance (in mice 3–8 mm) to get to their final site of differentiation. In contrast, those destined for the dentate gyrus of the hippocampus are born locally in the subgranular zone (SGZ) (see Fig. 1).

Neuronal recruitment has also been demonstrated in adult primates, including humans. Similar to rodents, cells in the adult primate hippocampus are born in the SGZ. Also in a similar manner to what has been described in adult rodents, new neurons born on the lateral wall of the lateral ventricles of adult monkeys migrate into the olfactory bulb where they differentiate into local interneurons. Interestingly, the migration from the SVZ to the olfactory bulb does not occur in adult humans, but has been inferred to take place in human embryos. This suggests that this migratory process stops sometime during development in the human brain. Gould and colleagues in 1999 proposed that limited neuronal recruitment may also occur in neocortex. However, other laboratories did not observe incorporation of new neurons in adult cortex.

In the case of the olfactory bulb and dentate gyrus, the recruitment of the new neurons in the adult has been firmly established. Analysis by electron microscopy has shown that newly formed cells in the dentate gyrus and the olfactory bulb of adult rats have the ultrastructure of neurons and receive synaptic inputs.

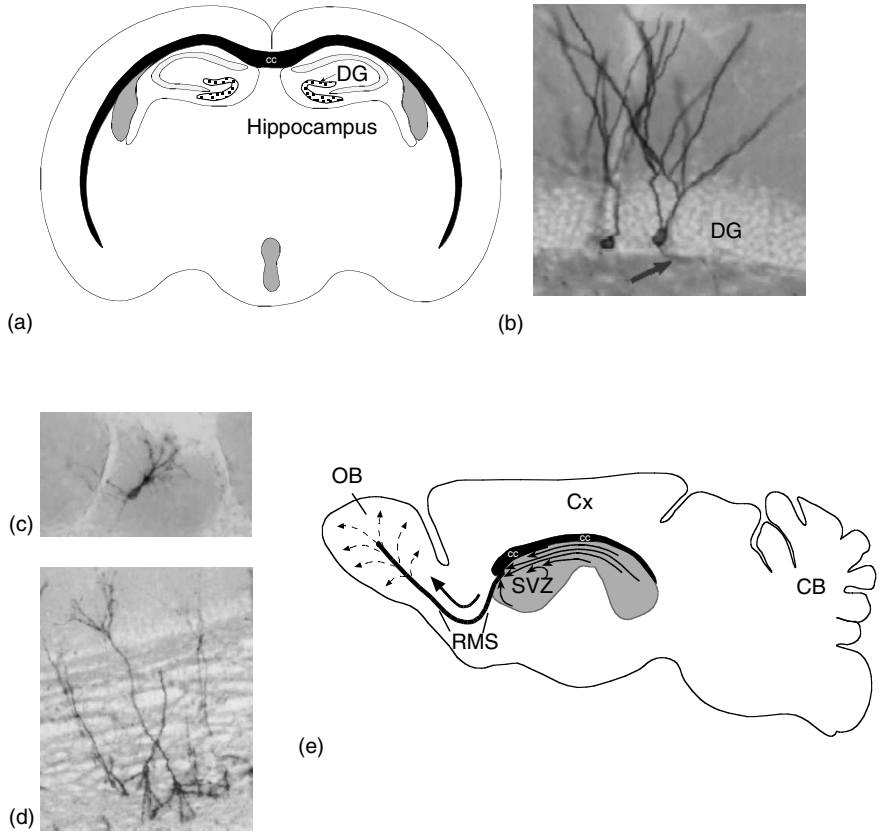

Fig. 1 Neurogenesis occurs in two regions of the adult brain. (a) Schematic cross-sectional view of the adult mouse brain at the level of the hippocampus. Retrovirally labeled progenitors in the subgranular layer of the dentate gyrus (DG) give rise to new neurons in the granule cell layer (b). Newly generated neurons, periglomerular cells (c) and granule cells (d) in the olfactory bulb are derived from labeled progenitors in the subventricular zone (SVZ). (e) The SVZ-OB system. Schematic sagittal view of the adult mouse brain with the OB to the left and cerebellum (CB) to the right. New neurons are produced throughout the SVZ (orange). The young neurons become aligned into long chains that form a series of interconnected paths throughout the SVZ. Once the chains reach the anterior SVZ, they join the rostral migratory stream (RMS), which leads the young neurons into the core of the olfactory bulb. Within the OB, cells disperse radially (dashed arrows) as individual cells and complete their differentiation into periglomerular cells (c) and granule cells (d). CX, Cortex; cc, corpus callosum. (See color plate p. xxxi).

In addition, newly formed cells in the dentate gyrus have axons that can be backfilled when a retrograde tracer is injected in CA3 of Ammon's horn. More recently, electrophysiological studies in slice cultures have demonstrated that new cells in the olfactory bulb and dentate gyrus display action potentials typical of neurons and are integrated into synaptic networks. These observations clearly establish the neuronal identity of new cells incorporated in the olfactory bulb and hippocampus.

The demonstration of adult neurogenesis in birds and mammals has changed the long-held dogma that no new neurons are formed in adults. These discoveries have raised the very basic question: which cells in the adult brain function as the primary progenitors or stem cells that make adult neurogenesis possible. The rest of this chapter will focus on the neural stem cells that are retained in the adult brain.

3 Identification of the Primary Precursors in the Adult Brain

During development neurons are born in specialized proliferative zones, generally in regions on the walls of the brain ventricle. As we have described earlier, this is also the case in adult birds where new neurons originate form progenitor cells in the wall of the ventricle. In adult mammals, cells born in the SVZ are also born close to the walls of the lateral ventricles, but neurons born in the SGZ are generated away from the ventricular system. In this section, we will discuss how these different germinal regions are organized and also discuss which cells are the stem cells for the continual generation of new neurons.

3.1 A Ventricular Zone (VZ) in Adult Birds: Radial Glia as Neuronal Progenitors

Classical studies have shown how radial glia serve as scaffolding for building the brain. As discussed below, until quite recently radial glia were considered committed progenitors of astrocytes, the most common type of glial cells in the brain; thus the name glia. Radial glia have their soma in the VZ, and possess a long process that extends toward the brain surface. These processes serve as guides for the migration of many young neurons from their site of birth in the VZ. Sometime after neuronal production ceases, radial glia in the mammalian brain migrate away from the VZ and transform into astrocytes. In contrast to mammals, radial glia persist in the adult brain of songbirds, as described earlier, and also in the adult brain of many species of cold-blooded vertebrates.

In adult canaries, new neurons are incorporated throughout most of the telencephalon, but not outside of it. This spatial restriction emerges during development around the time of hatching. As explained above, neurons are born in the walls of the lateral ventricles from which they migrate long distances to reach most areas of the telencephalon. The proliferative layer in the walls of the lateral ventricles in adult birds has many of the properties of the developing VZ. It is within this layer of cells that the primary precursor cells that support continuous adult neurogenesis reside. Proliferation occurs at higher rates in VZ ''hot spots'' where a large number of new neurons are born.

Young neurons born in these hot spots use the long processes of radial glia as guides to migrate away from the VZ. In this respect, the function of radial glia is similar to that described during the development of the cerebral cortex. However, a series of observations began to suggest that radial glia in adult birds may not only function as migratory guides but also as precursor cells. Neurogenic hot spots in birds are enriched for radial glia, and neurogenesis appears to be the primary function for these proliferative hot spots as no glial cells emerge from these regions. Surprisingly, radial glia divide, and their division correlates spatially and temporally with the appearance of new neurons in the proliferative hot spots.

This strongly suggests that radial cells in adult songbirds divide to generate the new neurons. Retroviral lineage studies in the adult avian telencephalon demonstrated radial glia in the same clones as that of new neurons, which was consistent with the model that radial glia gave rise to the new neurons. Radial glia in the adult avian brain also undergo interkinetic nuclear migration, a behavior typically associated with progenitor cells in the developing VZ. Adult avian radial glia also extend a single short cilium into the cerebrospinal fluid; primary cilia of similar structure and localization are found in neuroepithelial stem cells during embryonic development.

The above analyses strongly suggest that radial glial cells in the VZ of the adult avian brain function as the primary precursors of new neurons. The lineage and precise mode of division of radial glial in adult birds is not known. Nor is it known whether new neurons are produced directly from the division of a radial glia or whether the radial glia divide to generate intermediate progenitors that then generate the young neurons. The idea of radial glia as neuronal precursors was considered a peculiarity of adult birds, perhaps an adaptation for the continual generation of new neurons that is so widespread in the telencephalon of adult songbirds. In mammals, radial glia were considered to be in a lineage separate from that of neurons. However, as we will review below, this idea has begun to change.

4
Progenitors of New Neurons in the Adult Mammalian Brain

After more than a century of believing that the regenerative potential of the adult mammalian brain ended with development, the discovery of adult neurogenesis in restricted regions of the adult mammalian brain opened a whole new perspective. It suggested that neuronal progenitors and mechanisms to put these progenitors to work were in place at least in some regions of the adult brain. This raised hopes both for understanding a totally new mechanism of neural plasticity and for the possible use of this regenerative capacity for therapeutic purposes. One of the most basic questions was: which cells in the adult brain have this unique potential to give birth to the new neurons? It was well established that in mammals, unlike birds, radial glia are not retained in the adult brain, but transform into astrocytes at the end of fetal development as explained above. The origin of the new neurons in the SVZ and the SGZ, the two regions of the adult mammalian brain that continue generating new neurons in the adult, will be the theme discussed in this section.

4.1
Stem Cells Persist in the Adult Mammalian Brain

Before we understood the organization of adult germinal centers or the identity of the primary precursors of new neurons, studies of isolated cells *in vitro* made a very basic and important contribution. When cells from the adult brain were exposed to growth factors *in vitro* (in the initial studies on EGF or epidermal growth factor), a small subpopulation of the plated cells began to grow in suspension to form spherical clusters that were called *neurospheres*. Neurospheres have the interesting property of generating differentiated cells, including neurons, oligodendrocytes, and astrocytes when the growth factors are removed from the medium and the cells

are transferred onto a culture substratum that allows the cells to adhere to the tissue culture plate. Moreover, when primary neurospheres are dissociated and individual cells are placed again in nonadherent culture conditions with growth factors, a subpopulation of the cells in the neurosphere is able to generate secondary neurospheres that are also capable of generating differentiated progeny. Clonal cultures subsequently demonstrated that a single cell isolated from the adult brain can generate a neurosphere. Since self-renewal and multilineage differentiation are some of the basic defining properties of stem cells, these studies indicated that neural stem cells were retained in the adult brain. A similar conclusion was reached independently using adherent culture conditions with FGF (fibroblast growth factor) as the growth factor. FGF can also promote the growth of neural stem cells as neurospheres alone or in combination with EGF. Neurospheres have been isolated from other mammalian species including humans. It has been suggested that neurospheres could potentially provide a method for the amplification of neuronal precursors for therapeutic purposes. Neurospheres have become widely used in the neuroscience field to address questions on the regulation of self-renewal of neural stem cells, and to study factors that influence the differentiation of neural stem cells into specific types of neurons or glial cells.

Initial studies using EGF to make neurospheres used cells isolated from the entire striatum, which included parts of the walls of the lateral ventricle. Subsequent studies demonstrated that the self-renewing multipotent neurospheres were derived from a thin strip of the wall of the lateral ventricle. It is only on this wall that EGF-responsive cells capable of forming neurospheres are present. Interestingly, FGF-resposive neurospheres can be grown not only from the walls of the lateral ventricle but also from other ventricular walls, including the central canal in the spinal cord. FGF-responsive neural stem cells have also been isolated from regions of the adult brain, which apparently do not contain ventricular wall.

Interestingly, the populations of neural stem cells that respond to FGF or EGF are apparently different. There is some evidence suggesting that exposure to FGF induces the formation of EGF-responsive progenitors. This suggests that in the adult brain FGF may activate an earlier progenitor than EGF. The identification of the cells that respond to these growth factors *in vivo* is a topic of considerable interest and debate. We will next describe the organization of the SVZ and SGZ and describe their cellular composition. This will allow discussion of the possible cell types that give rise to neurospheres and provide an *in vivo* picture of how neurogenesis normally occurs in the adult brain.

5 Organization and Primary Precursors of New Neurons in Germinal Zones of the Adult Mammalian Brain

As explained above, neuronal birth in adult mammals has been demonstrated in two brain regions: (1) in the SVZ of the lateral ventricles and (2) in the subgranular layer (SGL) of the hippocampal dentate gyrus. In the adult mammalian brain, very few, if any, radial glial cells are retained into adult life, raising the question of the identity of the primary precursors for these new neurons.

5.1 The Subventricular Zone (SVZ)

The presence of large numbers of dividing cells in the SVZ has been known for more than a hundred years and is known to occur in many vertebrates including mice, rats, rabbits, hamster, dogs, monkeys, and humans. However, the fate of the large number of newly generated SVZ cells has been controversial. While pioneering work by Joseph Altman suggested that the SVZ could generate neurons, most other studies suggested that dividing SVZ cells serve as a reservoir of precursors for glial cells. Yet other investigators suggested that the dividing cells in the SVZ die soon after mitosis.

Direct demonstration that large numbers of neuronal precursors exist in the adult SVZ was obtained by culturing SVZ cells that had been labeled *in vivo* with [^{3}H]thymidine. *In vivo* adult SVZ cells generate new neurons that migrate to the olfactory bulb where they constantly replace interneurons, a process that also continues in adult primates. It has been suggested that SVZ cells may also give rise to neurons that migrate to other brain regions, but this process remains to be clearly demonstrated. In addition, the postnatal SVZ appears to be an important source of glial cells.

The cellular composition and organization of the SVZ has been described (Fig. 2). SVZ neuroblasts (type A cells), migrate in homotypic chains through a network of interconnecting pathways distributed throughout the wall of the lateral ventricle. These chains are ensheathed by slowly proliferating type B cells. B cells have the ultrastructural properties of astrocytes, including a light cytoplasm, thick bundles of glial fibrillary acidic protein (GFAP) positive intermediate filaments, gap junctions, glycogen granules, and dense bodies. Scattered along the chains of type A cells are clusters of rapidly dividing type C cells. Most of the SVZ is separated from the ventricle by a layer of multiciliated ependymal cells. Many of the chains of type A cells coalesce in the anterior and dorsal SVZ forming a restricted path of migration called the *rostral migratory stream* (RMS). The RMS is the pathway along which neuroblasts migrate from the SVZ to the olfactory bulb, where the neuroblasts differentiate into granule and periglomerular neurons.

Several lines of evidence indicate that a subset of SVZ astrocytes function as the primary neuronal precursors *in vivo*. Following infusion of the antimitotic drug cytosine-β-D-arabinofuranoside (Ara-C) into the adult mouse brain for six days, neuroblasts (A cells) and rapidly dividing C cells are eliminated. This treatment spares some SVZ astrocytes and ependymal cells. About 12 h after Ara-C removal, SVZ astrocytes begin dividing. Dividing SVZ astrocytes give rise to type C cells, which in turn generate neuroblasts. Within 10 days, the entire SVZ regenerates. Ependymal cells do not incorporate mitotic markers at any of the survivals studied, indicating that these cells are not the primary precursors of the new neurons.

GFAP-expressing astrocytes can be specifically labeled in transgenic mice expressing the receptor for an avian retrovirus under control of the GFAP promoter. SVZ astrocytes labeled with this method also generate type C cells, followed by neuroblasts that migrate to the olfactory bulb, indicating that under nonregenerating conditions SVZ astrocytes are also the primary precursors of the new neurons. As indicated above, a subpopulation of SVZ cells in the adult rodent brain can respond to EGF to generate neural

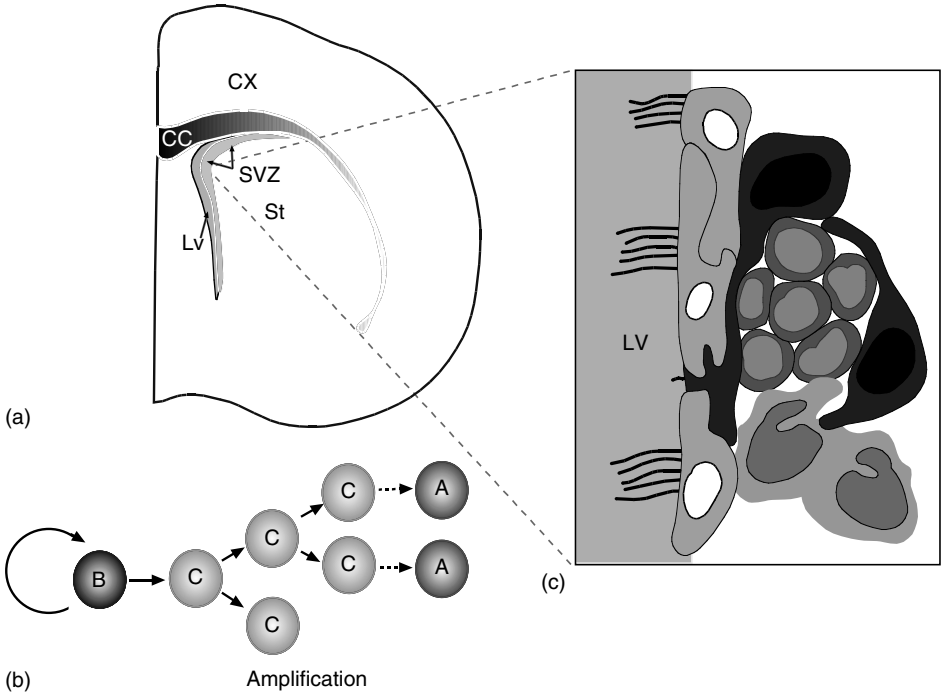

Fig. 2 Neurogenesis in the adult SVZ. (a) Cross-section of the adult mouse brain and (b) schematic illustration of SVZ composition and architecture; (c) expanded region. The SVZ lies adjacent to the lateral wall of the lateral ventricle (LV, tan). The chains of neuroblasts (A cells, red) destined for the olfactory bulb migrate as chains through glial tunnels formed by the processes of slowly dividing astrocytes (B cells, blue). Focal clusters of rapidly dividing precursors (C cells, green) are found scattered along the network of chains. Multiciliated ependymal cells line the wall of the ventricle (gray). Occasionally, an SVZ astrocyte extends a process with a single cilium to contact the ventricle. The lineage of olfactory bulb neurons has been described. SVZ astrocytes (B cells) act as neural stem cells in this region and divide to give rise to the rapidly dividing precursors (C cells) that in turn generate the neuroblasts that migrate to the olfactory bulb. (See color plate p. xxix).

stem cells *in vitro*. Cells derived from vitally labeled SVZ astrocytes respond to EGF signaling, both *in vivo* and *in vitro*. These cells can undergo self-renewal and can generate both neurons and glia. This suggests that SVZ astrocytes (B cells) correspond to the primary precursors of not only neurons, but also of neurospheres in the adult SVZ. Interestingly, astrocytes from other brain regions can also generate *in vitro* stem cells, but only if isolated from mice younger than 10 days. After this time, only astrocytes from the SVZ have this capacity. Importantly however, most of the EGF-responsive SVZ progenitors *in vivo* that give rise to neurospheres are not SVZ astrocytes, but rather the transit amplifying cells, the C cells. This suggests that as primary precursors (type B cells) are activated for proliferation and convert into type C cells, they retain self-renewal and multilineage potential if exposed *in vitro* to high concentrations of growth factors. Consistently, O2A progenitors, a transit

amplifying cell population from the optic nerve previously believed to be committed to the glial lineage, also generate cells with neural stem cell characteristics *in vitro* when exposed to growth factors.

Further verification that astrocytes are the neural stem cells comes from studies using transgenic mice expressing herpes simplex virus thymidine kinase (TK) from the GFAP promoter. Exposure to ganciclovir (GCV) leads to the production of a toxic metabolite, only in cells expressing TK, resulting in their selective killing. *In vivo* infusion of GCV into GFAP-TK mice for three days resulted in a nearly complete depletion (96%) of neurosphere forming cells from the SVZ. Together, the above results suggest that neural stem cells are contained within a population of cells classically considered to be differentiated macroglia.

Multiciliated ependymal cells have also been suggested to function as the neural stem cells of the SVZ *in vivo* and *in vitro*. However, several other studies do not support this interpretation. Most importantly, as mentioned above, there is no evidence that multiciliated ependymal cells divide *in vivo*. Ependymal cells do, however, play an important role in adult neurogenesis. Bone morphogenetic proteins (BMPs), which are powerful inhibitors of SVZ neurogenesis, are produced by SVZ astrocytes. This suggests that the neurogenic potential of many SVZ astrocytes is under constant inhibition by BMPs. Ependymal cells secrete noggin, which neutralizes the inhibitory effects of BMPs in the SVZ. Thus, the close interaction between the SVZ astrocytes and the ependymal layer is probably critical for the creation of a neurogenic niche.

Proliferation in the adult SVZ may be affected by lesions of the brain and of the corpus callosum, inhibition of nitric oxide, and stimulation of estrogen release in prairie voles. It will be interesting to determine precisely which cells are affected by the above manipulations. However, the problem is complex, as multiple cells divide in the SVZ, including the young neurons. Since these neuroblasts are migrating tangentially, apparent effects on BrdU labeling may not be due to changes in the rate of division of progenitors, but to the accumulation or depletion of neuroblasts resulting from changes in migratory rates.

The above observations demonstrate that SVZ astrocytes behave as neural stem cells *in vivo* and *in vitro*. This raises fundamental questions about the nature of SVZ astrocytes and how they differ from astrocytes in other brain regions. Astrocytes are very heterogeneous in structure, morphology, and function. Better markers are required to identify the different classes of astrocytes in the adult brain and, in particular, those that can function as stem cells. As mentioned earlier, neurogenesis also continues in the SGL layer of the hippocampus. In the next section, we will review recent work that suggests that astrocytes in the SGL also function as the primary precursors for new neurons.

5.2 The Subgranular Zone (SGZ)

The SGZ is the birth site of new neurons that become incorporated into the adult dentate gyrus of the hippocampus. In contrast to the SVZ or the adult avian VZ, the SGZ is not located close to the walls of the brain ventricles. It lies deep within the brain at the interface of the granule cell layer of the dentate gyrus and the hilus in the hippocampus. There is much interest in understanding the origin of these new neurons, as the hippocampus has such

an important function in learning and memory. Earlier work suggested that small darkly stained cells of "undifferentiated" appearance corresponded to the neural stem cells of the adult SGZ. *In vitro* studies also indicated that cells isolated from the adult hippocampus have neural stem cell properties *in vitro*. However, the identity of the cells *in vivo* that give rise to these stem cells in culture remains unknown.

In addition to the dark cells, astrocytes continue to divide in the SGZ of the adult hippocampus. Division of astrocytes was generally attributed to a process of local gliogenesis. This ongoing gliogenesis was thought to support neuronal function and neuronal turnover. However, more recent work suggests that SGZ astrocytes are the primary precursors of the new neurons of the adult hippocampus. We will next discuss how the SGZ is organized and the types of cells involved in adult hippocampal neurogenesis.

Two types of astrocytes have been identified in the SGZ, radial astrocytes, and horizontal astrocytes. Both types of astrocytes express GFAP, but only radial astrocytes express Nestin. Radial astrocytes have their cell bodies in the SGZ and have a prominent radial process that traverses the granular cell layer (Fig. 3). Radial SGZ astrocytes also have shorter tangential processes extending along the SGZ under the blades of the dentate gyrus. At the electron microscope, these cells have ultrastructural features of astrocytes similar to those of the SVZ, with a light cytoplasm containing intermediate filaments, and thin processes that intercalate between neighboring cells. Soon after labeling with a marker of DNA synthesis, such as BrdU

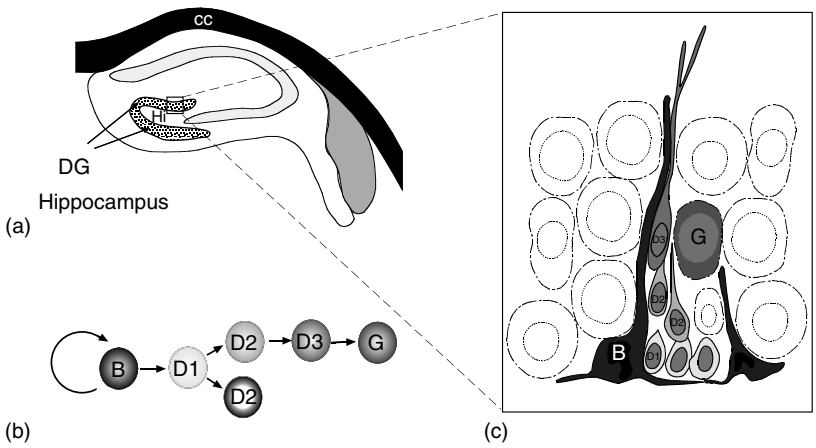

Fig. 3 Neurogenesis in the adult SGZ. (a) Cross-section of the adult mouse brain at the level of the hippocampus and (b) schematic illustration of composition and architecture of the SGZ and granule cell layer; (c) expanded region. SGZ astrocytes (B cells) have long radial processes that penetrate the granule cell layer and short tangential ones that run parallel to the SGZ. Dividing B cells generate immature, dark cells (D cells) that divide and mature into new granule neurons. D cells have been classified into three subtypes, D1, D2, and D3 that correspond to different stages in the maturation of the new neurons. The SGZ astrocytes (Blue cytoplasm, black nucleus); D cells (yellow or orange cytoplasm, gray nucleus), G: mature granule neuron (dotted, not filled). (See color plate p. xxiv).

or [^{3}H]thymidine, about half of the labeled cells in the SGZ correspond to astrocytes. Interestingly, with longer survivals after BrdU or [^{3}H]thymidine labeling, the number of labeled astrocytes rapidly decreases and the number of labeled GFAP-negative cells increases. A rapid decrease in the number of labeled GFAP-positive astrocytes with extended survival after BrdU injection has also been described in the dentate gyrus of adult rats. Close examination of this population of GFAP-negative cells that appears after increasing survival time revealed a small dark cell population (D cells). These cells probably correspond to the small dark cells previously suggested to function as the precursors of the new neurons (mentioned earlier).

Type D cells (or Type 2 progenitors as they were called in other studies), however, do not correspond to the primary precursors of the new neurons, but to an intermediate progenitor that is derived from the division of radial astrocytes. This was demonstrated by following the fate of dividing SGZ astrocytes after an antimitotic treatment and demonstrating that radial SGZ astrocytes cells give rise to D cells and granule neurons. Moreover, when transgenic mice that express the receptor for an avian retrovirus under control of the GFAP promoter are infected with an avian retrovirus expressing the reporter gene alkaline phosphatase, the dividing population of GFAP-expressing cells in the SGZ can be selectively labeled. One month after such selective labeling, labeled neurons are found in the granule cell layer. The neurons derived from the GFAP-expressing cells extended axonal projections into the CA3 region of Ammon's horn, indicating that they were incorporated into the normal circuitry of the hippocampus. Together, these experiments indicate that SGL astrocytes are the primary precursors that give rise to new granule neurons in the adult dentate gyrus through the intermediate D cells. As indicated above, neural stem cells can also be isolated and grown in culture from the adult hippocampus, but the *in vivo* cell type that gives rise to these stem cells *in vitro* has not been identified.

Detailed examination of the SGZ architecture has revealed a close interaction of radial astrocytes, the primary progenitors of the new neurons, with their progeny the D cells (Fig. 3). SGZ astrocytes and their processes form basketlike structures that nest tight clusters of D cells. Within these nests, D cells (Type 2 precursors) have cellular protrusions of different lengths and orientations, and begin expressing neuronal markers including Doublecortin, PSA-NCAM, Tuc4, NeuroD, Prox 1, and NeuN. Consistently, D cells have electrophysiological properties of young neurons. D cells have been classified into three subtypes, D1, D2, and D3, and shown to correspond to different stages in the maturation of the new neurons.

D1 cells are most immature, bearing no process or only a short one. Apparently, radial astrocytes divide asymmetrically to generate D1 cells that remain closely associated with the cell body of the progenitor astrocyte. Interestingly, D1 cells divide again to generate two D2 cells that bear a short process. Sometimes both daughter cells survive, but more frequently one of the daughters dies (Fig. 3). This is consistent with the finding that about half of all cells die during the maturation process. D2 cells then mature into D3 cells with a longer process that traverses the granule cell layer to become the primary dendrite of the newly formed granule neuron. D3 cells then mature into fully differentiated granule neurons.

Newly formed neurons then progressively lose PSA-NCAM from dendrites, cell body, axon and terminal synaptic arbor as they mature. During this maturation, the developing primary process of D3 cells, which gives rise to the dendritic arbor, remains closely associated with the radial processes of SGZ astrocytes. Thus D1, D2, and D3 cells remain closely associated with astrocytes throughout their maturation. Radial astrocytes appear to have a dual function; these cells give birth to the new neurons and support them throughout their maturation. They appear to provide scaffolding and probably support their development. The importance of astrocytes for supporting neurogenesis has also been demonstrated *in vitro* for SVZ and SGZ progenitors.

It is not known how much tangential dispersion of D cells occurs within the SGZ before these cells complete their differentiation. One possibility is that D cells do not migrate tangentially but remain largely confined to one radial domain, perhaps associated to their mother astrocytic cells. If this is the case, interesting hypotheses can be raised on the role that the primary precursor may play in the local control of neuronal addition.

The large radially oriented process of astrocytes that function as the primary precursors of new neurons may have important functions in relaying information from within the granule cell layer to the SGZ. This process may serve like an ''antenna'' to relay information from the granule cell layer and to the SGZ. This information may help regulate the proliferation of progenitor cells. Multiple factors can affect neurogenesis, and/or neuronal recruitment in the adult dentate gyrus, including adrenal steroids, the blockade of NMDA receptors, seizures, housing animals in enriched conditions, exercise, inflammation, and antidepressants. These different conditions may directly or indirectly affect the level of neuronal activity within the dentate gyrus and this may be detected by radial astrocytes inducing changes in the proliferation rate of these cells and in their progeny. It will be interesting to determine how these experimental paradigms affect the proliferation rates of astrocytes and D cells. Increased neurogenesis may require the induction of larger numbers of SGZ neural stem cells to enter the cell cycle. Interestingly, neuronal birth in the dentate gyrus increases following adrenalectomy, and this same condition results in a parallel increase in the proliferation of SGZ astrocytes. In this case, more astrocytes may become activated to accommodate the increased demand for new neurons following adrenalectomy. The identification of the primary precursors and of the intermediate cellular stages in the production of new hippocampal neurons will aid in the study of how neurogenesis is regulated in the adult mammalian hippocampus.

6 Organization and Primary Precursors of New Neurons in the Embryonic and Postnatal Mammalian Brain

In order to understand the developmental origin of adult neural stem cells and the derivation of adult germinal centers, we must be familiar with the identity and properties of embryonic neural stem cells. This section will discuss the organization of the early neuroepithelium and why these cells are believed to give rise to radial glia. Furthermore, we will discuss the structural and

stem cell functions of radial glia during development.

6.1 Radial Glia are the Neural Progenitors of the Developing Brain

As mentioned above, radial glia and their processes serve as scaffolding during brain development and, in particular, as guides for the migration of young neurons from their site of birth in the VZ to their final destination in different substrata of the developing brain. At the end of fetal development, radial glia in the mammalian brain retract from the ventricular and pial surfaces and transform into astrocytes that migrate into the underlying brain. As the name radial ''glia'' implies, these cells are thought to be glial cells. This is not only because they are immediate precursors of astrocytes but also because radial glial cells express markers and have morphological and ultrastructural characteristics of astrocytic cells.

Radial glia are thought to be derived from neuroepithelial cells, the earlier brain progenitors that form the neural plate and neural tube. In the embryonic neural tube, neuroepithelial cells contact both the ventricular and pial surfaces. As development proceeds and this neuroepithelium gives rise to the multilayered fetal brain, the distance from the ventricle to the brain surface greatly increases. Neuroepithelial cells transform into elongated radial glia by maintaining their ventricular and pial contacts. Radial glia and neuroepithelial cells have many things in common. Both cell types undergo mitosis with interkinetic nuclear migration. Radial glia contact the ventricular lumen into which they extend a single short cilium, which is very similar, if not identical, to the cilia found on the ventricular surface of neuroepithelial cells. Interestingly, this short cilium on radial glia and neuroepithelial cells is very similar to the one observed on adult neural stem cells (mentioned earlier). The function of this subcellular structure is not known, but it likely holds important secrets about neural stem cell regulation.

Both radial glia and neuroepithelial cells express the intermediate filament nestin, which is widely used to label neural stem cells in culture. This, together with the work in adult birds discussed earlier, began in the early 1990s and suggests that radial glial cells may be something more than just ''glia.'' After more than a century since Magini, Ramón y Cajal and others began to describe radial glia, or *spongioblasts* as they were also called at that time, the true nature of these cells has emerged. Radial glia are the stem cells of the developing CNS. A recent series of elegant studies in the developing mammalian brain have shown that radial glia divide and generate a wide array of brain cells including neurons. Radial glia isolated from embryonic mouse and rat neocortex can produce neurons and glial cells *in vitro*. Radial glia isolated during the time when a large number of neurons are formed in the cerebral cortex, produced mostly colonies containing neurons. In contrast, when radial glial cells are isolated after this peak in neurogenesis, they generate mostly glial or mixed colonies. This suggests that radial glial cells can generate both neurons and glia and that their potential changes with age.

The most direct proof of the progenitor function of radial glia comes from direct visualization of the behavior of fluorescently labeled radial glia in slice cultures. With this approach, one can directly observe cortical radial glia dividing asymmetrically to

produce young neurons, which then migrate into the cortex. Noctor et al. went on to make electrophysiological recordings from clonally related cells to confirm the identity of radial glia and their neuronal progeny. Taken together, the above clearly demonstrate that radial glia can generate neurons. More recent work indicates that in some instances radial glia divide asymmetrically, but produce neurons indirectly. The daughter cell moves away from the VZ into the SVZ and divides again to generate two neurons. This last pattern of neuronal generation, also having as an origin a radial glial cell, is reminiscent of that observed in the adult SVZ and SGZ, where a primary precursor first gives rise to a transit amplifying cell, which then divides to generate the neurons.

Radial glial cells appear to be much more than just ''glia'' or guide posts for neuronal migration. These complex cells are the stem cells that through repeated division directly or indirectly generate the amazing array of neurons and glial cells that shape the brain. Radial glial cells are not simple undifferentiated cells, as would be expected for a stem cell, and this fact had likely tricked us into believing for over a century that they were differentiated glial cells. Radial glia are large and complex cells that maintain specialized contacts with all strata of the developing brain; including the pial surface, blood vessels, neurons, and other progenitors in the VZ. These cells also form organized palisades that likely play an important structural role for the developing brain as classically thought. In addition to providing spatial alignment between germinal centers close to the brain ventricles and the more superficial brain regions where neurons take up residence, the long processes of radial glia could carry signals from more superficial strata of the developing brain mantel into the germinal epithelium in the VZ. This radially organized alignment system may be particularly important for the development and evolution of the mammalian neocortex.

The notion that radial glia are just scaffolding and support for embryonic brain development must change, as these cells are primary precursors for an enormous number of neurons. This new concept has immense implications for our understanding of the molecular and cellular basis of brain development. It is within radial glia that much of the program for brain histogenesis must unfold. Therefore, we must look to these cells to find the molecular switches that control the well-orchestrated generation of the different cell types that form the brain.

Contrary to what was expected, the cell type in the embryonic brain with the most complex and ''differentiated'' characteristics (long radial processes, elaborate cytoskeleton, complex endings in the pial surface, and contacts with blood vessels), the radial glia, turn out to be a primary precursor of neurons. Recent evidence indicates that these cells are also the precursors of adult neural stem cells, thus, revealing the lineage tree of neural stem cells.

7 The Lineage of Neural Stem Cells; Evolving Concepts

The above indicates that cells that have been classically considered as differentiated glial cells in the adult and the embryo correspond to the primary precursors of new neurons. The lineages leading to the formation of neurons and

glial cells were classically considered to diverge early during embryonic development. In this traditional lineage tree, astrocytes and radial glia were drawn in one branch, while neurons were placed in a separate one. On the basis of the above findings, this concept has begun to change. In this last section, we will discuss how neural stem cells in the developing and adult brain are likely to be contained within what was classically considered a macroglia lineage – neuroepithelium-radial glia-astrocytic cells – (Fig. 4). It is from this central stem that the differentiated lineages in the brain emerge.

Since the discovery of glial cells in the nervous system in the middle of the nineteenth century, these supportive cells have been considered the end product of differentiation rather than the stem from which other cells were derived. Initially, it was believed that glial cells had a mesenchymal origin and corresponded to the connective tissue of the brain. This idea was overturned by Wilhelm His, who showed that glial cells were

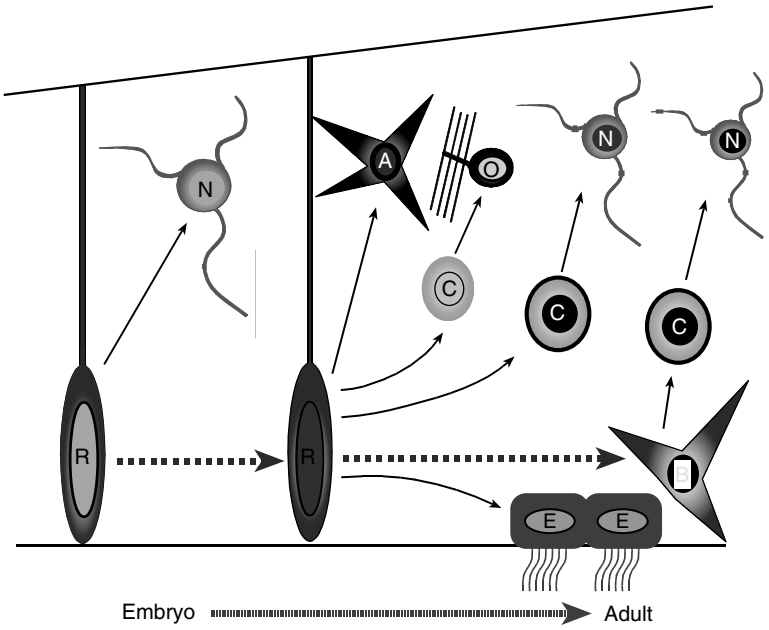

Fig. 4 Development of neural stem cells from the embryo to the adult. Primary progenitors in the embryo correspond to radial glia (R) in blue. These cells produce different generations of neurons (N, red) during development either directly, or indirectly through transit amplifying progenitors (C cells, green). Radial glia also generate oligodendrocytes (O, black) and ependymal cells (E, gray). It is not known whether single radial glia generate these different cell types or whether radial glia are lineage-restricted *in vivo*. Radial glia also turn into parenchymal astrocytes (A, black-blue) and germinal region astrocytes (B, blue-black). The latter continue to divide in the adult brain and generate neurons (N) and oligodendrocytes (not shown) through transit amplifying cells (C)]. The neural stem cell lineage is contained within what was classically considered an astrocytic lineage (Blue cells and arrows). (See color plate p. xxxiii).

derived from the so-called ''spongioblasts'' (what we now know as radial glia). From his work emerged the dominant hypothesis that in the early neural epithelium, predetermined precursors produced either neurons or glia. This concept of a separate origin for neurons and glia has remained very influential in neuroscience until fairly recently.

Neurons and glial cells are not as separate as once thought. Work in insects, for example, has shown that neurons and glial cells may be produced from a final division of a progenitor. Work in vertebrates has also suggested that both glial cells and neurons may be derived from a common progenitor. Other studies, however, continue to support the idea that glial-restricted and neuronal-restricted progenitors give rise to the corresponding differentiated cells in the brain. Both lineage-restricted precursors and multipotential stem cells may exist in the brain and as such these two camps may not necessarily subscribe to mutually exclusive ideas.

Two major findings suggest that stem cells are contained within what was earlier considered a glial-restricted lineage; the demonstration of radial glia as progenitor cells of not only astrocytes but also neurons, and the identification of multipotent precursors with astrocytic characteristics that support ongoing neurogenesis in the adult brain. This is not to say that all cells with astrocytic characteristics are stem cells. In fact, the name ''astrocyte'' has been used to describe a wide array of cells in the brain, including some (e.g. stellate astrocytes) that do not divide and appear to be terminally differentiated glial cells. Clearly, progenitor potential is inherited by some astrocytes, and this suggests that a continuum between embryonic and adult neural stem cells may exist to form the stem cell lineage in the brain. The question is: which cells in the developing brain are the progenitors of the adult neural stem cells?

One hypothesis is that it is the radial glial cells. These cells are known to give rise to astrocytes, some of which may be the ones that retain progenitor function in the adult germinal niches. Notch is believed to maintain cells in a proliferative progenitor state and inhibit neuronal differentiation. When Notch is activated in early neuroepithelial cells, it promotes radial glial identity, consistent with the idea that radial glia are derived from neuroepithelial cells and that they possess stem cell potential. This same study suggests that Notch activation in the early neuroepithelium promotes astrocytic identity in the adult brain including the SVZ. This observation lends support to the idea that radial glia in the lateral wall of the lateral ventricle may transform into the SVZ astrocytes that continue to function as stem cells in the adult. Direct evidence linking radial glia in development with adult stem cells has recently been obtained.

In mice, as in other mammals, most but not all radial glia have transformed into astrocytes by birth. A subpopulation of radial glia persists in the lateral wall of the lateral ventricle of newborn mice. Interestingly, these radial cells are precisely in the region where the adult germinal SVZ will develop. This offered an opportunity to directly test whether radial glial cells in this region serve as progenitors of adult neural stem cells. The cell bodies of neonatal radial glia line the lateral wall of the lateral ventricle and form a VZ. Their long basal processes radiate outward, curving through the striatum toward the surface of the brain. The disappearance, within the first week of life, of radial glia from

the lateral ventricular wall correlates with the appearance of GFAP+ astrocytes, suggesting a possible link between these two cell populations. Taking advantage of their unique long processes that curve around the striatum, a technique was developed to selectively and permanently label a small cohort of radial glia. When a virus expressing the DNA recombinase, Cre, is injected into the lateral striatum near the brain surface, it infects the radial glial cell processes and is transported to their cell bodies in the VZ. Specific labeling of these radial glial cells can be attained when the infection is performed in transgenic mice carrying a reporter gene behind a transcriptional stop element flanked by Cre-recombination sites. Examination of the fate of these labeled radial glial cells at varying time points after the initial injection, demonstrated that radial glia give rise to olfactory bulb granular and periglomerular interneurons, and striatal and SVZ astrocytes. This is consistent with the traditional concept of radial glial cells being precursors of astrocytes and with the more recent view that radial glia are also neuronal progenitors (mentioned earlier). Interestingly, however, these radial glial cells also give rise to two other cell populations that were not known to be derived from radial glia: oligodendrocytes and ependymal cells. This demonstrates that this population of neonatal radial glia act as multipotent progenitors, but it remains unknown whether individual radial glia are multipotent *in vivo*. When individual labeled radial glia were placed in culture, they generated neurospheres. The neurospheres grown from radial glia self-renewed and differentiated into neurons, astrocytes, and oligodendrocytes, indicating that striatal radial glia act as true neonatal stem cells *in vitro*. Most importantly, some of these neonatal stem cells transformed to generate the neurogenic stem cells of the adult SVZ (Fig. 4). These results strongly support the hypothesis that neural stem cells are contained within the radial glia–astrocyte lineage.

The evolving view suggests that differentiated cells, including neurons and glia, are derived from neural stem cells which include neuroepithelial cells, radial glia, and astrocytes. Progenitors in the VZ of the developing mammalian brain are programmed spatially and temporally to produce different types of neurons. It is, therefore, within neuroepithelial cells, radial glia, and astrocytes that these molecular programs unfold for the generation of different cell types. As developmental time progresses and these cells convert into adult progenitors, neural stem cells constantly change. The most rapid change probably occurs during embryonic development, as neuroepithelial cells and radial glia adjust their genetic program to produce the different types of neurons and glial cells required for assembly of the nervous system. The temporal control of neurogenesis is illustrated in Fig. 4, by showing neurons of different sizes and shades produced at the different developmental stages. This is an oversimplification of a process that includes multiple reiterations and many more cell types, affecting not only neurons but also glial cells. Some of the genetic control for the generation of different types of neurons has begun to be uncovered in the insect brain, and this is likely to become a dominant theme in vertebrate neural development and in trying to understand neural stem cell regulation. Thus, while we postulate the neuroepithelium-radial glia-astrocyte as the lineage within which neural stem cells are contained, this does not mean that all these cells are equivalent. The types of neurons and glial cells produced at each

developmental stage may be quite unique and dependent on an internal program that these cells carry. Therefore, in the strictest sense, neural stem cells *in vivo* are probably not self-renewing, especially during development.

8 Concluding Remarks

A profound change in concepts is taking place in our understanding of neural development and the nature of neural stem cells. The demonstration of adult neurogenesis has not only challenged long-held dogmas about brain development and plasticity, but has allowed us to study the nature and origin of neural stem cells. We have reviewed above a string of discoveries leading to the suggestion that neural stem cells are contained within a lineage of neuroepithelial cells, radial glia, and astrocytes, which was once considered a lineage leading to the generation of only differentiated glial (support) cells. These new concepts could have important implications for how we think about development and help us devise new strategies for brain repair. Perhaps most surprising is that neural stem cells are not simple ''undifferentiated'' progenitor cells. They are structurally quite complex, with long processes that interact closely with other cells in the brain and most prominently with their own progeny. Thus, in addition to being progenitors, they also appear to be true supportive cells as had been originally attributed to glia. This combined function – progenitor and support – may be inherited from a time in evolution when epithelial cells first ''invented'' how to make nerve cells. As suggested by Ramón y Cajal almost a century ago, astrocytes may be nothing more than modified epithelial cells. An important challenge for the future is to try to identify the different subtypes of astrocytes in the adult brain and learn to distinguish those that retain stem cell potential.

Keywords

Bone Marrow–Derived Cell
Any cell that was present in the bone marrow at the time of extraction before transplant into a new host; includes hematopoietic stem cells, stromal cells, and other cell types.

Cloning
The introduction of a donor nucleus into an enucleated oocyte to produce an embryo.

Heterokaryon
A cell containing multiple distinct nuclei derived from different types of cells.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 13

Programming
A global change in gene expression profile resulting in a specialized, mature differentiated cell.

Reprogramming
Global change in gene expression profile resulting in a switch from one cell type to another.

Stem cells are responsible for providing a source of differentiated cells in adult tissues that undergo renewal or repair. Considerable progress has been made recently in the identification and characterization of stem cells in adults. They have been the focus of intense interest because of their potential therapeutic use in restoring form and function to damaged tissues. Stem cells in postnatal animals have been identified in specific locales, but another promising and less well-characterized population of stem cells are circulating cells derived from the bone marrow (BMDC). Advances in nuclear transplantation and the observed plasticity of gene expression and phenotype reported in multiple phyla, show that adult cells, including derivatives of HSCs, have a remarkable capacity to be reprogrammed. Irrespective of the mechanism by which reprogramming occurs, fusion or differentiation in response to the microenvironment, the potential for new gene expression patterns by BMDC (bone marrow–derived cell) progeny in recipient tissues holds promise for developing cellular therapies for both proliferative and postmitotic tissues.

1 Introduction

The concept of stem cells continues to evolve and the list of examples of stem cells is growing. Yet, the need for rigorous experimental verification coupled with problems of semantics and long-held dogma make identification of a cell as a stem cell difficult. The necessary functional characteristics of stem cells as well as the physical criteria that endow them with tangible qualities that can be used to detect, isolate, and manipulate them remain elusive. There is no universally agreed upon definition of a stem cell, yet most investigators claim to know one when they see one.

This chapter concerns ''adult'' stem cells, as distinct from ''embryonic'' (ES) stem cells. For the purposes of this review, all stem cells existing in postnatal animals are ''adult.'' Like all somatic cells, adult stem cells are presumably derivatives of embryonic stem (ES) cells, although the ontogeny of diverse adult stem cells remains unclear, since to date lineage tracing has not been performed. ES cells studied in tissue culture generally are cell lines selected for their ability to proliferate indefinitely *in vitro*. There is no evidence that such a characteristic bears relevance to the *in vivo* functions of ES cells and it is likely that these cells have acquired properties that differ from their cell of origin in the blastula. Since ES cells can be

made to grow and differentiate *in vitro*, similar expectations are often made of adult stem cells. As is the case with ES cells, such manipulations are unnatural, and place a different set of demands on cells that may have no bearing on their function *in vivo*. A case in point is that although to date cartilage can be produced in a culture dish, it has never been possible to obtain function in joints after implantation in mammals. Therefore, it is necessary to distinguish the biology of ES and adult stem cells as they exist and function in an organism from what they or their progeny can do in a dish.

A conceptual paradox arises regarding one of the most commonly ascribed attributes of a stem cell: the potential for self-renewal. As defined, self-renewal is the ability to yield progeny that are identical to the parent cell. Self-renewal is known to occur at a functional level based on serially transplanted hematopoietic stem cells (HSCs) in mice that continue to repopulate the lineages of the blood. However, the property of self-renewal is more complex than it first appears, as HSCs cannot be serially transplanted indefinitely and HSC function decreases with age. Self-renewal carries the connotation of the ability to divide without limit (as ES cell lines appear to do). However, should self-renewal be a property of stem cells *in vivo*, it must be under strict control. Moreover, a common determinant of stem cells *in vivo* is that they *rarely divide*. In fact, some of the most elegant studies used to track stem cells *in vivo* exploit the property of label retention. A prerequisite for label retention is limited division to avoid dilution. Accordingly, the number of divisions that stem cells undergo in the adult (although more than other somatic cells) is quite limited and has been estimated for a number of tissues to be in the range of 100 to 1000 during the lifetime of the organism. These confounding findings raise the question as to whether self-renewal, or the ability to be cultured extensively in a clonal fashion should be considered a property essential to stem cells that exist naturally *in vivo*. We suggest here that the importance of clonality in stem cell biology is limited to providing experimental material for *in vitro* manipulation in order to work with homogeneous cell populations uncontaminated by other cell types. Its relevance *in vivo* remains unclear; certainly extensive self-renewal without specialization does not appear to be the norm in adult tissues.

Another attribute often ascribed to adult stem cells is their potency, or the number of different types of differentiated progeny that can be produced by a given stem cell. ES cells, by definition, give rise to all the cell types of the body. Adult stem cells differ in that respect. Most ''stem cells'' found in adult tissues are largely responsible for producing a few different specialized cell types, or possibly only one type (satellite cells in the case of muscle, for example). While this characteristic may reflect intrinsic differences in the ability of cells to express different patterns of genes, an equally plausible explanation is that it may reflect differences among cells in exposure to factors in their *in vivo* microenvironment. These factors influence experimental findings and are responsible for much of the debate surrounding the ''nuclear plasticity'' or differentiative potential, of cells found in postnatal animals.

All tissues that undergo renewal or repair are associated with relatively less differentiated cells that divide and differentiate to replenish cells lost in response to injury or in the course of aging. The number of different cell types that can arise from any given progenitor may vary, is poorly understood, and is a subject of

debate and interest. In addition, such considerations are essential for defining stem cells versus the more specialized progenitors and then precursors to which they give rise, for example, in hematopoiesis. Consequently, in this chapter we avoid a strict definition of ''adult stem cells,'' as any definition is likely to exclude or underestimate the contribution of cells with a critical role in tissue repair, the essential property of a stem cell *in vivo*. Thus, terminology can hinder progress by providing constraints to the acceptance of novel findings that do not fit a definition intrinsic to a long-held dogma. Such semantic problems have contributed to the confusion that plagues the stem cell field, in general, especially with respect to experiments using bone marrow–derived cells (BMDC) or the subpopulation of BMDC that are HSCs.

Terms such as ''plasticity,'' and ''transdifferentiation'' have a range of different connotations, and thus clarification based on historical definitions may be useful. The phenotypic conversion of one cell or tissue type into another has been termed ''metaplasia,'' and the literature is replete with examples in humans. ''Transdifferentiation,'' on the other hand, is a specific type of metaplasia involving a change in differentiated phenotype. As classically defined, the criteria for transdifferentiation of a cell are very specific: initially the cell must exhibit a mature, specialized stable phenotype, followed by a change to another specialized stable phenotype, not necessarily involving an intervening cell division. As used here, a ''mature'' cell refers to a cell type that performs a function, with stable, identifiable characteristics of the specific tissue or organ system to which it contributes and is often postmitotic, for example, neurons, keratinocytes, and cardiomyocytes. On the other hand, ''plasticity'' is characteristic of all examples of nuclear reprogramming, including cloning, heterokaryons, or metaplasia. Simply put, plasticity means ''the ability to change or adapt.'' It is a descriptive term that relies on context. To minimize confusion, we propose that the term ''plasticity'' always be qualified and used in a specified context; for example, plasticity of nuclear gene expression, plasticity of cell morphology, plasticity of the differentiated state.

A clear distinction between that which occurs in life and that which we can induce is essential, yet often confused. With increased technological advances, these differences may become more obscure, affecting results and their interpretation. Until recently, frequent and easily discernible fates of cells were reported. Now it is possible to detect extremely rare events. Technological advances have revealed unexpected properties of cells, such as the ability of HSCs or their progeny in adults to incorporate into muscle fibers. The repertoire of individual HSCs (and their progeny) was not supposed to include participation in skeletal muscle and expression of muscle-specific genes. Is this heresy, a rare fluke of nature, or due to the restrictions scientists have imposed on the HSC inherent in its name and definition? Below, we summarize the current state of knowledge regarding stem cells that function in postnatal animals. We then discuss our hypothesis that what will ultimately dictate the medical value of any particular postnatal cell as a stem cell is its potential to be ''programmed'' or ''reprogrammed, which is a property intrinsic to its nuclear chromatin structure. Furthermore, we speculate that the ability to alter this property and remodel chromatin at a molecular level can enhance the plasticity of any given cell and consequently its utility.

2
Characteristics of Adult Stem Cells

Stem cells have been characterized in a number of different adult somatic tissues in which turnover is the norm. Stem cells are not known for cells that are not generated postnatally, such as Purkinje neurons. Moreover, cells of most somatic tissues, other than the blood, do not circulate and remain relatively localized within one region of the tissue throughout the lifetime of the cell. Accordingly, somatic stem cells have been found within the tissues to which they are known to contribute in adulthood (see Table 1). The concept that the circulation can be an alternate route for somatic stem cells to reach and contribute to injured target tissues has arisen as a possibility in the past few years as markers of blood (GFP (green fluorescent protein), Y chromosome, and β-galactosidase) and methods for definitively resolving single cells expressing more than one marker (laser confocal microscopy) have come available. Transit of non-HSCs via the circulation would require functions in addition to those known to be performed by localized stem cells (extravasation and homing) heretofore thought to be limited to hematopoietic cells. To be convincing, physical incorporation into tissues must be coupled with novel patterns of gene expression. This process may be termed *reprogramming*, or more aptly in the case of stem cells, ''programming'' since a stem cell should not need to be *re*programmed to do something that is part of its natural function. One concern is whether the programming or reprogramming that occurs attains the frequency required to affect the function of the recipient tissue. This second requirement is key for any natural property of stem cells in living animals. However, rare events if real do not preclude use of a particular cell therapeutically for tissue regeneration. A clear understanding of the biology underlying such naturally occurring events may allow manipulation of cells and augmentation of their ability to perform new functions.

The designation of a cell as a ''stem cell'' has been limited to cells residing within proliferation-competent tissues that give rise to progeny that exhibit tissue-specific morphology and function. By marked contrast to ES cells, cultured cells from adults display a much lower propensity to differentiate into a broad range of cell types, and primary cultures are often difficult to establish. In most cases, adult stem cells have exhibited oligo or unipotent abilities (see Table 1 for known examples and their unique characteristics). The characterization of stem cells in adults is very much a work in progress. A detailed account of each of the cell types currently designated as ''stem cell'' in adult tissues is beyond the scope of this text and the reader is referred to a number of excellent reviews and primary articles. Below we focus on one central principle of stem cell function: the ability to induce the nucleus to express a specific repertoire of genes, thereby modifying cell identity in order to maintain, replace, or rescue a particular tissue.

3
Plasticity of Gene Expression

The recently discovered capacity of adult BMDCs to contribute to nonhematopoietic tissues suggests that they may reprogram their nuclei for functions other than blood. Nuclear transplantation (cloning) and cell fusion in nondividing heterokaryons and subsequently cloning, provide historical evidence for plasticity of mammalian gene expression. These

Tab. 1 Best-characterized stem cells found in adult tissues. For each tissue listed, stem cells have been located in specific anatomic sites with reasonable certainty and stem cell function has been demonstrated *in vivo* without intervening cell culture. To this date, only the hematopoietic stem cell can be prospectively isolated at the single-cell level based on phenotypic characteristics, and shown to function *in vivo*.

Tissue	*Location/niche*	*Defining characteristics in vivo*	*Surface markers defined for prospective isolation?*	*Differentiated progeny*
Skin	Follicle bulge, basal epidermis?	Label retaining, repopulate skin lineages after transplant	No	Hair follicle, sebaceous gland, epidermis
Blood	Bone marrow and peripheral blood	Repopulate blood lineages after transplant	Yes	Lymphoid, myeloid, erythroid cells
Skeletal muscle	Muscle fiber periphery between sarcolemma and basal lamina	Distinct anatomic location, fuse with and generate new myofibers after transplant	No	Skeletal myofibers
CNS	Periventricular zone	Label retaining, migrate to olfactory bulb or hippocampus	No	Neurons, astrocytes, oligodendrocytes
Gut epithelia	Basal region of intestinal crypts	Single cells regenerate entire crypts after irradiation	No	Enterocytes, goblet cells, paneth cells, enteroendocrine cells
Melanocyte	Lower permanent portion of the hair follicle	Label retaining, distinct anatomic location, regenerate pigmentation after transplant	No	Melanocyte
Skeletal	Marrow	Formation of a complete bone organ after transplant	No	Chondrocytes, osteocytes, adipocytes
Testis	Seminiferous tubule basement membrane associated with Sertoli cells	Restore sperm production after transplant	No	Spermatogonia

fundamental observations provide clear evidence of nuclear plasticity and serve as a starting point for understanding this developing field and its potential applications to regenerative medicine. Examples from numerous publications reveal that the potential exists at the genetic, cellular, and organismal levels for cells to assume new functions: gene expression patterns can change, differentiation can be manipulated, and cells can incorporate into tissues from which they did not originate. Consideration of the evidence leading to this conclusion describes the current state of the field. A consideration of the progress in the understanding of molecular mechanisms for remodeling chromatin may determine whether there are insurmountable blocks to using endogenous genetic or cellular complements (directly or after *ex vivo* manipulation) to repair the body. The goal of this chapter is to draw attention to the fundamental concept that plasticity of gene expression (required of stem cells) is widespread in mammalian cells, and provide the reader with evidence that this idea is supported by decades of experimentation.

The most direct way to investigate the capacity of a nucleus to express a new set of genes is to expose it to new intracellular factors and observe how it responds. Nuclear cloning, the introduction of a donor cell nucleus into an enucleated oocyte to produce an embryo, was first studied in amphibians. The results showed for the first time that differentiation and development do not require loss or irreversible inactivation of genes. The disparate interpretations of the early results are instructive *vis-a-vis* the current controversy surrounding the behavior of BMDC, HSC, and their derivatives in different settings. Briggs and King first reported that transplantation of nuclei from frog blastulae into enucleated oocytes yielded swimming tadpoles. They observed that irrespective of developmental stage, donor nuclei from a given lineage typically gave rise to normal tissues of the same lineage, but to abnormal tissues from other lineages. These experiments led them to conclude that differentiated donor nuclei are restricted in their developmental potential. Diberardino demonstrated that differences in cloning efficiency were, in part, related to the cell cycle of the donor nucleus, which had to switch to the rapid cycle typical of the egg. Nuclei derived from cells that were further along in development lost totipotency, presumably because they were more differentiated, had slower cell cycles and were therefore more difficult to activate. In other nuclear transplant experiments, Gurdon showed that when tadpoles were used as the source, some normal adult frogs could be produced using nuclei derived from differentiated intestinal endoderm. By contrast with Briggs and King, Gurdon heralded these findings as strong evidence for the plasticity of gene expression, and concluded that genes are not permanently inactivated, but instead can be reawakened, even in differentiated cells. Some caveats remained. Attempts to generate adult frogs from nuclei derived from adult animals were unsuccessful. King favored the interpretation that reprogramming of differentiated nuclei was limited, and that Gurdon's results likely represented contaminated transplants that included less differentiated cells. Nonetheless, Gurdon's bold interpretation stimulated thinking in the field of differentiation. Remarkably, confirmation of these results in mammals was not forthcoming for decades.

Despite the experiments in amphibians, 20 years later their relevance to mechanisms of differentiation in mammalian

cells had still not gained acceptance. Experimentally induced fusion of different cell types using viruses or the chemical polyethylene glycol became a powerful method to study gene expression changes after exposure of nuclei to new cytoplasm. Studies using synkaryons (cell hybrids that proliferate and exhibit nuclear fusion) first showed the existence of trans-acting repressors and activators, but gene activation was only transient because of cell division and the consequent loss of chromosomes. These studies were extended by fusion of cultured cells to form multinucleate, stable heterokaryons, in which each nucleus remained distinct and intact. Such nondividing cell fusion products allowed changes in gene expression to be monitored over time. Gene expression patterns depended on the nuclear ratio or relative gene dosage, and the consequent balance of factors present in the cytoplasm at any given time, showing that differentiation is dynamic and continuously regulated.

Clear evidence of reprogramming adult somatic nuclei evolved as investigators learned to manipulate heterokaryons. In early work with heterokaryons, Ringertz showed that fusion of rat myoblasts and chick erythrocytes caused the nuclei of the erythrocytes to swell and chromatin to become diffuse, but reprogramming was not observed. When transformed lines of mouse muscle cells were fused in tissue culture with rat cells in high serum medium that did not favor differentiation, gene repression, not activation was observed. However, when stable heterokaryons were produced in low serum medium in the presence of inhibitors of cell division, fused diploid mouse muscle cells and nontransformed human diploid cells derived from all three embryonic lineages, endoderm (hepatocytes), ectoderm (keratinocytes), and mesoderm (fibroblasts), were shown to activate a number of previously silent genes (muscle) for the first time. These results indicated that the differentiated state could be altered, even in specialized cells derived from human adults. Critical to these findings were the cell type used (nontransformed cells), the medium (which favored differentiation not proliferation), and a means of preventing mitosis and unequal chromosome segregation. Similar results were also obtained using similar methods with other differentiated cell types. Together, these *in vitro* heterokaryon studies established that the expression of genes that had been previously ''silenced'' during development and differentiation could be reactivated by cytoplasmic factors present in somatic cells, without the passage of nuclei through the oocyte or exposure to sequential factors characteristic of embryogenesis that was necessary for amphibian cloning. The heterokaryon studies first conclusively demonstrated that the differentiated state in mammals was not terminal, but could be altered.

The cloning of sheep nearly 15 years later confirmed the findings in heterokaryons and cloned amphibians. Micromanipulation of the much smaller, more delicate mammalian oocyte was pivotal to the success of nuclear transplantation in mammals. Techniques for injecting oocytes, rather than zygotes, and other conditions for cloning mammals were progressively improved in the 1980s and 1990s culminating in 1997 with the successful cloning of Dolly, a sheep derived from the transplantation of an adult mammary epithelial cell nucleus into a mammalian oocyte. Mammalian cloning has now been replicated in a number of species, including humans, due to a progression of technological advances.

The low efficiency of mammalian cloning (less than 1% of all nuclear transfers produce live offspring) left open the question of the cell of origin of successful clones, with the possibility that tissue-specific stem cells were the source of the effective nuclei. That concern was addressed first in cloning experiments using mature B and T lymphocytes, and has recently been laid to rest with the generation of live mice from unambiguous, fully differentiated, postmitotic olfactory neurons. These experiments leave no doubt that even ''terminally'' differentiated cells in mammals have nuclei that retain the remarkable capacity to be reprogrammed to totipotency and generate all the cell types necessary to form an intact animal.

From a practical standpoint, the efficiency of mammalian cloning has not improved since the first cloned mammals were reported. In addition, surviving cloned animals often continue to have a high incidence of defects, for example, large offspring, placental problems, and arthritis. These abnormal phenotypes are likely to be the result of epigenetic rather than genetic abnormalities, because they are not passed on to the offspring of affected cloned animals. Accordingly, a major effort is being directed at identifying the factors that are responsible for promoting the orderly silencing and reactivation of genes.

In summary, we now know that the cytoplasm has the capacity to direct reprogramming, and that at least in oocytes, reprogramming to a totipotent state can occur. Therapeutic cloning via the derivation of ES cells derived from somatic nuclear transfer into oocytes has already proven to be a viable approach to cell therapy with the cure of RAG 2 deficient mice. Oocytes and sperm have also been produced from existing ES cell lines, potentially bypassing the need to repeatedly obtain oocytes from live humans for the purpose of cloning, and associated ethical problems. Approximately half a century has passed since the pioneering work of Briggs and King, and Gurdon, and although the practical limitations of low efficiency, high cost, and an incomplete understanding of reprogramming mechanisms must be overcome, it seems likely that therapeutic cloning will play a role in regenerative medicine.

Evidence that plasticity of gene expression (nuclear reprogramming) occurs naturally *in vivo* is important, since both cloning and PEG-induced heterokaryon formation are examples of extreme, experimental manipulations. Examples of *tissue* metaplasia in humans include bone formation in scars and muscle, as well as conversion of one type of epithelium to another in the respiratory tract, the urinary bladder, and in the esophagus (Barrett's metaplasia). Metaplasia can also be induced experimentally. For example, pancreas can be converted to liver *in vitro* and *in vivo* in response to diverse factors In Drosophila, conversion of one imaginal disc to another in response to changes in homeotic gene expression is another example of metaplasia. In urodeles, a differentiated limb muscle cell can dedifferentiate and yield muscle, cartilage, and connective tissue progeny, and seminal studies of newt lens regeneration provide the most well-known examples of transdifferentiation. Like urodeles, zebrafish also have a marked capacity for regeneration, but as in humans, rigorous documentation of cellular metaplasia in zebrafish by tracking labeled cells, has yet to be reported. Finally, in axolotls, individually labeled spinal cord glial cells can dedifferentiate after tail amputation, and give rise to mature mesodermal (and neural) progeny, a definitive germ layer switch. Thus, in

response to injury, cells in differentiated tissues exist that can change and exhibit different phenotypes in lower animals as well as mammals, and the mechanisms may be evolutionarily conserved.

Notably, in humans metaplasia usually occurs in response to pathological conditions (e.g. gastroesophageal reflux in Barrett's esophagus). Indeed, it is unclear whether there are examples, in humans, of metaplasia as a component of normal development, and the cells responsible for tissue metaplasia in mammals have not been defined. It is possible that reserve cells for each different cell type are present as distinct entities in metaplastic tissues. By contrast, in mammalian lung, electron microscopy has revealed that morphological characteristics and organelles of two different cell types can appear in one cell during metaplastic conversion suggesting that in some cases multiple gene expression patterns are available to a particular cell in response to environmental changes. Taken together, the many examples of metaplasia are a testament to the intrinsic ability of cells to alter significant patterns of the genes they express in response to their *in vivo* environment.

The mammalian examples of metaplasia described above do not involve transcendence of embryonic lineages or apparent transit of cells via the circulation. Intense investigation in mammals has recently been directed at seeking evidence of metaplasia across embryonic lineages both for fundamental interest and potential therapeutic benefit. This research has primarily focused on BMDC in adults, which have efficient access to all tissues of the body via the circulation.

When the first report appeared demonstrating that bone marrow cells could contribute to muscle in mice, it was unclear whether this was a sporadic event or of fundamental physiologic significance. Using bone marrow from a transgenic animal expressing the myosin light-chain enhancer driving β-galactosidase (B-gal), muscle fibers expressing the reporter gene were found in transplant recipients. There followed a number of reports of similar findings, using marrow cells marked genetically with B-gal, Y chromosome, and GFP. Such cells were reported to be present in the brain, liver, heart, skeletal muscle, and epithelia of the kidney, lung, and skin. The incidence was generally low (0.01 to 0.1% of total cells) and many of the initial observations were not reproduced. Although semantics seems to confound results and their interpretation, there is justifiable concern about the validity of reported findings and each should be met with appropriate skepticism, as well as rigorous examination of the stringency of the methodologies used and accuracy of the conclusions drawn. To be conclusive, experimental findings must be replicated by others.

The emerging picture is that the contribution of BMDC to nonhematopoietic tissues is a rare but real event under normal physiological conditions. This contribution can be significantly increased in response to tissue stress or damage, for example, in liver In another case, damage to muscle either by local toxin injection or exercise resulted in a markedly higher BMDC contribution, and it may be possible to increase this frequency further. While recognizing that other excellent examples exist, we focus below on two that are illustrative: skeletal muscle and Purkinje neurons, which have been extensively studied by our group.

The identification of one cell type within bone marrow with the capacity to contribute to muscle was a critical finding. Since the bone marrow contains ''stromal''

cells with the ability to differentiate into various tissues, it was not clear whether stromal cells were responsible for the BMDC contributions to liver and skeletal muscle following bone marrow transplant. Single-cell transplants have now shown definitively that ckit+, sca-1+, lin-HSC progeny not only reconstitute all lineages of the blood, but also incorporate into muscle in lethally irradiated mice. Whether additional cells in marrow share this capacity and can transit naturally to other tissues via the circulation remains to be determined.

BMDC also contribute to a population of cells that are unique to the cerebellum. In both mice and humans, BMT-derived nuclei can be found in Purkinje neurons. In mice, this is a low frequency event that increases over time after BMT, and most such Purkinje neurons exist as binucleate heterokaryons. The use of transgenic mice harboring the Purkinje specific promoter, L7, showed that BMDC nuclei that are present in heterokaryons exhibit dispersed chromatin and express the L7 promoter. Heterokaryon formation also occurs in damaged multinucleated muscle fibers. These findings suggest an intriguing mechanism by which complex, postmitotic structures may incorporate genomic material from endogenous cells in adulthood.

The contribution of bone marrow to other tissues appears to represent an additional example of metaplasia in mammals. However, available data do not address the question of whether BMDC contribution to other tissues is functionally significant in normal life. From a therapeutic standpoint, proof of principle has already been achieved with the survival of tyrosinemic fumarylacetoacetate hydrolase (FAH) mice following HSC transplantation. Thus, the degree to which this phenomenon can be manipulated for therapeutic goals is an important line of investigation.

Two different mechanisms have been proposed whereby BMDC contribute to nonhematopoietic tissues (see Fig. 1). Either mechanism ultimately involves nuclear reprogramming. Initial reports of ''plasticity'' in adult stem cells suggested that a developmentally immature BMDC could alter its typical course of differentiation to that of nonhematopoietic tissues. Therefore, BMDC could function as traditional stem cells for other tissues. This first mechanism implies a response to extracellular signals that are detected by the BMDC and result in an alteration of gene expression and differentiation along an alternative developmental path. Such a process could, in theory, result in mononuclear cells, either directly or via a tissue stem cell intermediate. Examples that have been reported include BMDC-derived kidney epithelium, pulmonary epithelium, and pancreatic islets. Three groups have also reported BMDC in the satellite cell position, underneath the basal lamina, expressing muscle stem cell markers Although skeletal muscle may be the most amenable system for discerning stem cell intermediates, it also has inherent complexities, as the end state via stem cell or direct fusion is the same: a multinucleated fiber. The strongest evidence to date that BMDC can be reprogrammed as mononuclear cells has recently been shown in pulmonary epithelium using the Cre/Lox system to exclude fusion.

As evidence for the second mechanism, fusion, the heterokaryons formed between BMDC and muscle or BMDC and Purkinje neurons are perhaps the clearest examples. In the case of fusion, reprogramming is achieved by cytoplasmic factors that may

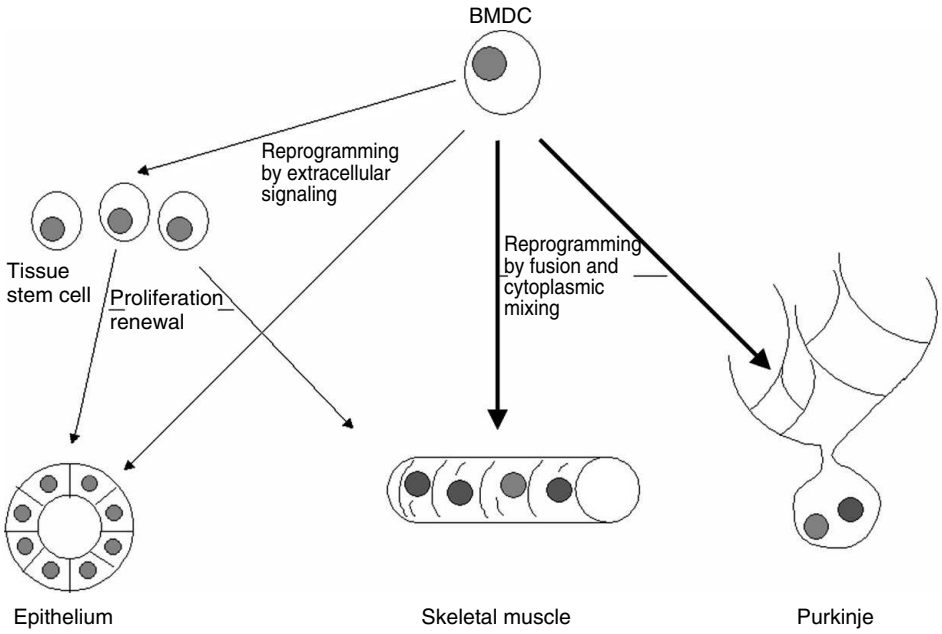

Fig. 1 Schematic representation of the possible mechanisms of BMDC incorporation into nonhematopoietic tissues. As discussed in the text, not all mechanisms are well established *in vivo*, and each may occur to a different extent or not at all in different tissues. Thick arrows indicate mechanisms that are better supported in the current literature. First, nuclear reprogramming can occur in cells in response to extracellular signals to yield a mature differentiated cell; second, nuclear reprogramming may first result in differentiation into a tissue-specific stem cell that has the ability to generate mature, fully differentiated cells; third, nuclear reprogramming is achieved when the nucleus of the donor cell is exposed to intracellular signals within a mixed cytoplasm following cell fusion. Fusion of BMDC directly with recipient cells is most clearly shown in Purkinje neuron x BMDC heterokaryons, but most probably also occurs in skeletal muscle that exists naturally as a syncytium.

be similar to those associated with reprogramming during cloning, or in the nuclei of heterokaryons formed *in vitro*. Initial reports of contribution of BMDC to nonhematopoietic tissues by fusion described the phenomenon as ''illegitimate,'' ''mere,'' or ''random.'' However, time has granted a new respect for fusion. It is becoming clear that fusion of BMDC with other tissues is a specific process limited to particular donor and recipient cells. Moreover, it occurs naturally *in vivo*. A number of molecules have been implicated in cell–cell fusion in eukaryotic species, some of which may play a role in BMDC fusion. It will be interesting to determine whether fusion mechanisms are evolutionarily conserved and if cells that are involved in BMDC contribution to other tissues fuse by similar mechanisms.

In mammals, why fusion has remained a property of some cells except in the case of muscle or sperm and egg, is unclear. We propose that the observed fusion of BMDC with cells of other tissues may represent a way for cells from different parts of the body with diverse histories to contribute to one another.

A plausible significant impact from such a cellular interaction is demonstrated by rescue of the FAH mouse. And while other models are currently lacking, one could envision situations in which a cell suffers a deleterious loss-of-function mutation and is rescued by expression of a reprogrammed, wild-type copy present in a donated nucleus. If such scenarios occur, a provocative and as yet unanswered question arises: if a BMDC exists that can self-renew and yield progeny such as myeloid cells amenable to fusion, reprogramming, and rescue of a defunct Purkinje nucleus, is it functioning as a Purkinje stem cell?

As the factors involved in the control of gene expression at the molecular level are identified, approaches may emerge for increasing the efficiency of programming and reprogramming. Chromatin remodeling by histone acetylation or deacetylation, methylation of histones or DNA, and other mechanisms such as SWI/SNF comprise the basic mechanisms of gene activation and repression. Pharmacological or genetic interventions that target such remodeling factors may prove useful for relaxing chromatin in order to direct gene expression toward desired end points.

4 Conclusion

The previous half-century has provided the foundation and paved the way for stem cell biology and therapy. We have learned that (1) genetic material is generally not lost during development and differentiation, (2) the cytoplasm of the oocyte as well as somatic cells has the ability to reprogram gene expression, (3) most genes, even in terminally differentiated cells, can be reactivated, (4) a single somatic nucleus has the replicative capacity to yield enough tissue for a whole new organism, and (5) in life, cells change their phenotypes, and in some cases, nuclear gene expression is reprogrammed across lineages. These findings indicate that the theoretical roadblocks based on long-held dogma and old paradigms that might have precluded the use of cells from one source to contribute to another have been overcome.

Nonetheless, much of what we have observed and learned comes from unnatural biological perturbations. Even the incorporation of BMDC into nonhematopoietic tissues is not only extremely rare under most conditions, but experiments necessarily depart from natural circumstances. Furthermore, the efficiency with which incorporation occurs remains low and will not be of clinical interest until the incidence can be increased. Thus, the practical utility of BMDC and their advantages and disadvantages will become clear relative to ES and other stem cells with further experimentation. Another unresolved question regarding the current understanding of *in vivo* contribution of bone marrow to other tissues involves the potential for proliferation of reprogrammed cells. The different mechanisms by which BMDC may contribute to nonhematopoietic tissues are each potentially useful, but have different implications. Differentiation via a stem cell intermediate implies the ability to expand reprogrammed cells, as does fusion followed by reduction division. By contrast, direct fusion with postmitotic cells that cannot proliferate but form stable heterokaryons could serve as an alternative means of tissue repair. Fusion to form heterokaryons presents the intriguing possibility that a structurally complex, nondividing cell could

be rescued by a cell from another tissue. Nuclear donation and subsequent reprogramming may already constitute an elegant solution used by nature in humans and mice, and one that could be capitalized upon for therapeutic purposes. In one potential application relevant to either mechanism, BMDC could be engineered to serve as cellular delivery vehicles for therapeutic genes to nonhematopoietic tissues.

A distinction between the potential mechanisms required for nuclear reprogramming is important to consider when drawing parallels between cloning and heterokaryons formed *in vivo*. Nondividing heterokaryons observed *in vivo* are not subject to many of the demands that cloned nuclei are. In addition, the more limited gene expression patterns required by *in vivo* reprogramming (BMDC only need to express genes of one different cell type) may have different mechanistic requirements. Whereas the gold standard test for reprogramming in nuclear transplantation is the generation of an animal, the requirements for reprogramming BMDC nuclei are less extensive if not less stringent.

If the existence of technological hurdles and questions of degree or "low frequency" had daunted researchers of the last half-century, then cloning would not have persisted beyond a dream or the subject of science fiction. Perhaps the progress of cloning research, leading to therapeutic (not reproductive) cloning may predict the future with respect to the field of nuclear reprogramming and its applications to regenerative medicine. Like cloning, we should approach the biology and technology of adult stem cells with vigor, rigor, and persistence.

Keywords

Blastocyst
Stage in development of the preimplantation embryo that follows the morula stage where cells are segregated into the ICM and trophoectoderm.

Centrosome
The organizing center for chromosome replication.

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 13
Edited by Robert A. Meyers.

ISBN: 3-527-30650-1

Chimera
An organism that contains cells from more than one set of gametes.

Cloning
The generation of a genetically identical copy. Therapeutic cloning is the term used when a cell line, rather than a unique individual, is generated.

ES-like
Cells that appear to be pluripotent and share some similarity with ESC lines.

Gastrulation
A series of morphogenetic movements that reorganize the developing embryo into three germ layers.

Homologous Recombination
The process of replacing a specific sequence in the genome by a modified sequence such that the inserted sequence is placed in a defined location.

ICM
Inner cell mass or a group of cells that is destined to contribute to the embryo proper.

IVF
In vitro fertilization. A term encompassing the process of generating fertilized preembryos using artificial reproductive technology.

MAPC
Multipotent adult progenitor cells.

Morula
An early stage of preembryo development.

Preembryo
A fertilized embryo prior to implantation in the uterus.

SCNT
Somatic cell nuclear transfer. A process by which somatic cell nuclei are inserted into an enucleated fertilized egg.

Self-renewal
The process by which stem cells generate daughter cells whose properties are identical to the parent cell.

Stem Cells
A population of cells with specialized properties that distinguish them from other cells. Stem cells are classified on the basis of the tissue from which they were isolated and their differentiation ability.

Teratocarcinomas
Tumors derived from transformed germ cells that often include differentiated cells from all germ layers. Teratomas are similar nonmalignant tumors derived from implanted ES cells.

Trophoectoderm
The outer layer of cells after embryo compaction that is destined to contribute to the developing placenta.

Embryonic development prior to implantation of the embryo in the uterus includes a stage of blastocyst formation, where the initial mass of cells is segregated into an inner cell mass destined to contribute to the developing embryo and an outer layer of cells that will contribute to the fetal portion of the placenta. Embryonic stem cells (ESCs) are cells derived from the inner cell mass of the developing preembryo that can be propagated indefinitely in culture. ESCs are characterized by the expression of a characteristic set of markers, the ability to self-renew indefinitely a lack of contact inhibition, atypical cell cycle regulation, the ability to form teratocarcinomas in nude mice, and the ability to differentiate into ectoderm, endoderm, and mesoderm either *in vitro* or *in vivo* after injection into blastocysts. This constellation of abilities distinguishes ESCs from all other cell populations, including adult stem cells.

The unique ability of ESCs to be propagated in culture, undergo genetic manipulation, and, nevertheless, retain the ability to contribute to all portions of the developing embryos, including germ cells, has been utilized to generate transgenic animals in which specific genes are introduced or removed. Such transgenic and knockouts have been utilized effectively to generate animal models of human disease, to develop improved strains, and to study critical aspects of development.

The ability to manipulate ESCs such that subsequent generations are derived solely from cultured manipulated cells, coupled with recent advances in deriving primate (including human) ESC lines has generated much excitement and hope as well as profound ethical concerns and considerable debate on how best to proceed.

1 Embryonic Development

Prior to the union of human gametes, the oocyte first requires timed completion of meiosis. This vital step does not occur throughout a woman's life, rather oocytes are arrested at the first meiotic division until puberty when small numbers mature competitively during the reproductive years. Maturation is complete at the ''one day'' event of ovulation that occurs in a regular, approximately, monthly cycle. Oocytes that are not fertilized are not retained, and, in humans, oocytes can be successfully fertilized only during a short

period after ovulation. Sperm cells mature from spermatic stem cells through a sequential process that has been well characterized. Spermatic stem cells are, in turn, generated from primordial germ cells that are ''set aside'' during early embryonic development. Generally, tens of millions of sperm are present in an ejaculate of which only one will successfully fertilize the mature oocyte. Sperms that fail to fertilize are discarded.

Fertilization initiates the process of cell differentiation. Maternal inherited mRNA regulates the initial developmental events, and embryonic transcription is not initiated till later. Once the sperm enters the egg, its DNA-associated proteins are replaced by oocyte histones. The two pronuclei become enveloped with oocyte-derived membranes, which fuse and begin the zygote's mitotic cell cycle. The sperm centrosome controls the first mitotic divisions and zygotic genomic activation occurs around day 4 at the morula stage. Embryonic development initiates with a series of cleavages to produce eight undetermined and essentially equivalent blastomeres. The pattern of cleavage is well coordinated by cytoplasmic factors and, in mammalian eggs, is holoblastic and rotational. The individual blastomeres are initially totipotent until the morula begins compaction and when cells initiate polarization. During compaction, cell boundaries become tightly opposed and cells are no longer equivalent. Cells in the inner cell mass contribute to the embryo proper, while cells on the outside contribute to the trophoectoderm. The blastocyst forms approximately 24 h after the morula stage by the development of an inner fluid-filled cavity, the blastocele. While genomic DNA is inherited from both parents, mitochondrial DNA is inherited from only the mother. Paternal mitochondria transferred at the time of sperm entry are discarded by a process that is little understood.

Human eggs are generally smaller than other eggs (about 100 μm), are usually fertilized within the fallopian tubes, and undergo cellular division in a defined mileu as they migrate toward the uterus. Cellular division follows a predictable 12- to 18-h cycle, resulting in 2 to 16 cell preembryos over the first several days.

Implantation is the process by which the compact zonula is thinned and the blastocyst released to implant. The blastocyst must first hatch from the thinning *zona pellucida* by alternating expansion and contraction, and this process of hatching is critical to further development. Implantation of the hatched blastocyst requires several steps, including apposition, attachment, penetration, and trophoblast invasion, and cannot occur till the first cell specification into trophoectoderm has occurred. As the trophoblast is developing to form the fetal component of the placenta, the endometrial lining of the maternal uterus is undergoing a decidual reaction to generate the maternal component of the placenta.

Simultaneously, the inner cell mass undergoes a process of gastrulation. Gastrulation is defined as a process of complex, orchestrated cell movements that vary widely among species, but include the same basic movements. These include epiboly, invagination, involution, ingression, and delamination. Thus, several major developmental events have taken place as the fertilized egg is migrating from the site of fertilization (fallopian tubes) to the body of the uterus over a period of four days. At all stages, the egg is shielded from the external environment, initially by the zonula and subsequently by the trophoectoderm, but is accessible to *ex utero* manipulation (see Fig. 1). It is important to emphasize

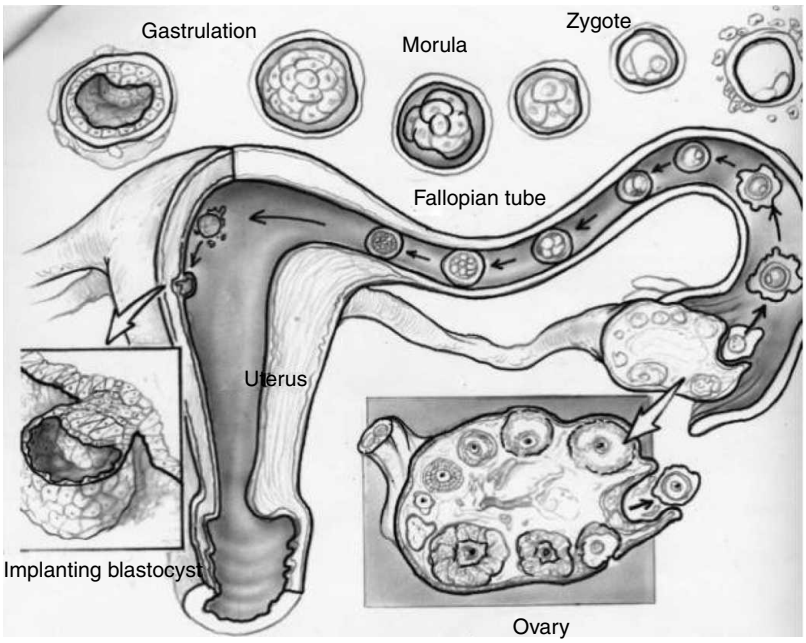

Fig. 1 Normal development of the preimplantation embryo – The mature follicle is released into the fallopian tubes, where it is fertilized by the sperm. The zygote travels down the fallopian tube, undergoing maturation to implant into the uterine wall four to – five days after fertilization. Figure by Tony Med Art.

that these important developmental events have occurred prior to implantation and well before blood vessel growth and heart development. The early-stage fertilized egg that has not yet been implanted has been termed a *preembryo* to distinguish it from the implanted embryo.

As our understanding of early developmental events has increased, our ability to safely manipulate the reproductive process has also increased, and various strategies to assist the reproductive process have been devised. Manipulation of the preimplanted embryo has been feasible for the past three decades, and *in vitro* fertilization, which was first performed 26 years ago, is now a common procedure. Currently, well over a thousand established clinics worldwide provide reproductive services, and approximately 1 to 3% of all live births are achieved with the utilization of some IVF services. The widespread use of IVF technology has led to the availability of large number of embryos that are in excess of reproductive requirement or have been stored for years against future need, and detailed rules governing the procurement, storage, use, gift/donation, destruction of blastocysts have been developed with perhaps the most regulated being the process of derivation of embryonic stem cell lines from human blastocysts.

2 Derivation of ES Cells

Embryonic stem cells (ESCs) are cells harvested from the inner cell mass (ICM) of

the developing preembryo that were destined to develop into all major derivatives of the developing embryo including germ cells that would ultimately develop into the next generation. Remarkably, cells harvested from the ICM can be maintained in culture over prolonged time periods (years) such that they retain this pluripotency in culture. Cultured ESCs differentiate into multiple phenotypes, both in a culture dish and after implantation into immunocompromised mice and contribute to an entire embryo after being injected back into a blastocyst that is subsequently implanted and allowed to develop to term.

ESCs can only be derived from a particular stage of embryonic development prior to implantation, at the time when the preembryo (preimplantation embryo) has separated into an inner cell mass and an outer trophoectoderm. The derivation process involves separating the inner cell mass from other portions of the developing preembryo by mechanical, enzymatic, and immunological means, or by laser surgery. The intact inner cell mass is placed in a dish with feeder cells and complex media, and colonies that propagate and have the appropriate characteristics are selected for additional growth to develop an ES cell line (see Fig. 2). The efficiency of the derivation process is variable, ranging from 30% to less than 1%, and varies among species and even among different strains of the same species. For example, it has been very difficult to obtain ES lines from rats, while it has been comparatively easy to obtain them from mice. Among mice as well, ESC lines can be produced with high efficiency only from

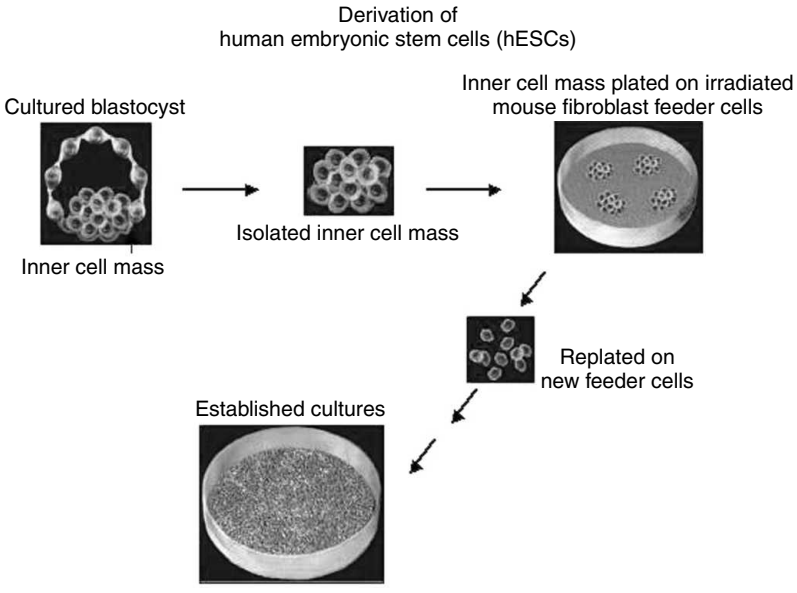

Fig. 2 Derivation of ES cell lines – A diagrammatic representation of the process of ES cell derivation. Cells of the ICM are removed and placed on support cells and propagated in ES cell medium. Cells are periodically tested for marker expression, and stability and lines of pluripotent cells are derived. A single blastocyst may generate one to three lines. Figure courtesy Dr J. Lebkowski (Geron).

some strains. It is unclear as to what dictates success, though the consensus suggests that subtle differences in the timing of rapid developmental change that characterize this stage underlie the differences observed.

ESCs were first described in mice, and were first established in the 1980s by Gail Martin, D. Solter, and others. In most cases, ESC isolation was performed by either mechanical dissociation of the embryo or immune ablation of the cells surrounding the ICM. Subsequently, ES cell lines have been derived from multiple other species, including fish, equines, bovines, and primates. Variations in success have been reported with some difficulty in isolation of ES lines from rats and some strains of mice.

Jamie Thomson and colleagues utilized excess human preimplantation embryos to harvest the inner cell mass and propagate it in culture to derive several lines from human blastocysts. These human cell lines have been maintained successfully in culture for over three years and retain their ability to differentiate into all major components of the embryos (see Fig. 3). Subsequent successful derivations have been performed in multiple laboratories. Prior to August 9, 2001, over 70 independent derivations had been reported. These derivations and cell lines obtained from them have been termed *presidential lines* under the Presidential (George W. Bush – USA) decree that only these lines will be eligible for federal funding. Additional lines have been subsequently derived and, currently, over hundred human embryonic cell lines have been established, and their ability to differentiate into exoderm, endoderm, and mesoderm

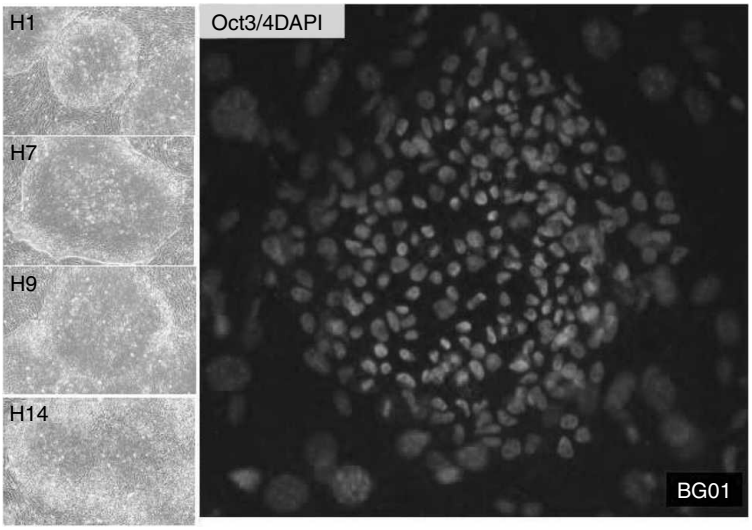

Fig. 3 ES cells – Typical colonies derived from four human ES cell lines are shown. On the right, a colony from a fifth line has been stained with an antibody to Oct3/4 (ES cell marker) and has been counterstained with a nuclear dye to show that the colony consists of a uniform population of undifferentiated cells. Photographs courtesy Dr M. Carpenter (Robarts Research Institute) and Dr X. Zheng (NIDA).

repeatedly demonstrated. Progress in the field has been rapid, and the efficiency of isolation has improved from 1% to about 30%. Variant lines derived from abnormal embryos diagnosed by isolation of single cells from suspect genetically abnormal embryos have been established and, more recently, ES lines from compound blastocysts generated from enucleated fertilized eggs, and somatic nuclei from donor cells have been established.

Ongoing research in the field of ESC derivation has been modified by a variety of factors that include the relatively broad patent issued to Wicell, covering all pluripotent ES lines such as the US president's decision to allow federal funds to be used only for lines derived prior to August 9, the differences in regulation across countries, the longer time period required to propagate hES cells, the proprietary interests of ES cell companies that invested in deriving cell lines, and the broad ethical concerns raised by the ability to manipulate the human genome. Apart from the ethical issues related to consent for donation, destruction of potential human life and other fundamental issues and important concerns have been raised about cloning. The ability to generate human embryonic stem cells and the ability to perform somatic nuclear transfer and successfully clone mammalian species raises fears, often fueled by limited information about cloning human beings. This relatively recent technological breakthrough has created maximum controversy, primarily because of its perceived potential to be used or misused on a large scale. It is useful to remember, however, that at each stage of technological sophistication, profound ethical issues have always been raised and publicly debated. Consensus will no doubt be reached, and one can look forward to accelerated progress once controversies are resolved.

3 Basic Properties of ES Cells

ES cells appear to be differ from all other cell populations in the long-term self-renewal ability, lack of contact inhibition in culture, regulation of the cell division cycle, their ability to form teratomas in immune compromised mice, and their ability to contribute to the germline after injection into blastocysts. These functional differences reflect in differences in gene expression, presence of cell surface epitopes, growth factor, and cell culture requirements, and serve to distinguish ESC from other stem cell populations derived from different developmental stages or different tissues. A few other embryonic cell types have been shown to retain some of the properties of ICM-derived ES cells, but so far no adult stem cell or even a stem cell derived from late fetal stages has shown a similar profile.

Much of what we know about ESCs comes from experiments performed on mouse ES cells. ES cells, irrespective of which strain of mouse they are derived from, grow as compact, well-defined colonies of tightly packed cells that are attached to each other by gap junctions. Cells have a high nuclear-to-cytoplasm ratio, with each cell typically having one or more prominent nucleoli. ESCs require growth factors to permit their growth, and these factors appear to be present in fetal bovine serum and in feeder cells prepared from mouse embryonic fibroblasts. In addition, supplementation with leukemia inhibitory factor (LIF) will enhance growth of mESC and may substitute for requirement of coculture with fibroblasts. Other genes

identified that are required for the maintenance of the ESC or required for proper maturation of the blastocyst include a variety of growth factors, transcription factors, and other regulatory genes, a few of which are discussed briefly below. Oct4-/- embryos die before the egg cylinder stage, and ES cells cannot be established from Oct4-/- cells. Levels of Oct4 are critical to the fate of the cells. Low cells lead to differentiation into trophoblast giant cells, while high levels cause differentiation into primitive endoderm and mesoderm. Sox-2 is another transcription factor that is thought to cooperate with Oct4 to maintain undifferentiated cells and activate key ES cell–enriched genes. Fibroblast growth factor (FGF4) is required for multiple aspects of early development and FGF4-/- embryos fail to develop after implantation, and ICM-derived cells do not proliferate *in vitro*. Foxd3/Genesis is another transcription factor that may be required for early embryonic development. Nanog is a recently identified homeodomain containing a transcription factor that appears critical for the proper self-renewal of ES cells. BMPs (bone morphogenetic proteins) and other members of the TGFß family appear to be important at multiple stages of early embryo development. BMP acting via BMPR1 can enhance self-renewal of ESC and substitute for the serum in ESC medium. FGFs and wnts are thought to play an important role in the process of gastrulation.

Examination of ESCs has made clear that multiple pathways that interact with each other at multiple levels regulate their proliferation and self-renewal. These pathways appear similar to the pathways activated as the ICM matures *in vivo* to generate embryonic tissue. ESC lines therefore serve as a useful and possibly unique model of early stages of embryonic development. These early stages have been very difficult to study in humans.

4 Similarities and Differences among ES Cells Derived from Different Species

The ability to compare ES cells from human and rodents has allowed one to assess conserved pathways likely to be important in ES cell self-renewal. Nanog, Oct3/4, sox, rex, utf, tert, connexin, Glut-1, Dicer, DNMT, and so on all appear to be conserved, and are likely to be important in ES cell self-renewal. This conservation of key pathways suggests a core ES cell identity that is conserved across species. This core identity that would include Oct, Sox, REX, UTF, TERT, and so on will be clearly distinct from genes expressed in other ''adult/non ES'' stem cell populations. Many, but not all, of these pathways are likely conserved between species (see Fig. 4).

Differences in gene expression and regulation have been reported as well, and, surprisingly, these differences have included genes important for self-renewal and survival of mouse ES cells. For example, Oct3/4 homologs likely do not exist in chicken embryos, while LIF signaling, which is critical for ES cell self-renewal in rodents, does not appear to be critical or even required for human ES cells. No paralogs of *E-Hox*, a gene critical for mouse ES cell self-renewal and differentiation, have been identified in humans. Eras, which is required for the growth of mouse ES cells, appears to be a pseudogene in humans. Human ES cells appear capable of differentiating into trophoectoderm, while mouse cells lack this capability. Species differences in equivalent populations are to be expected; however, the number of

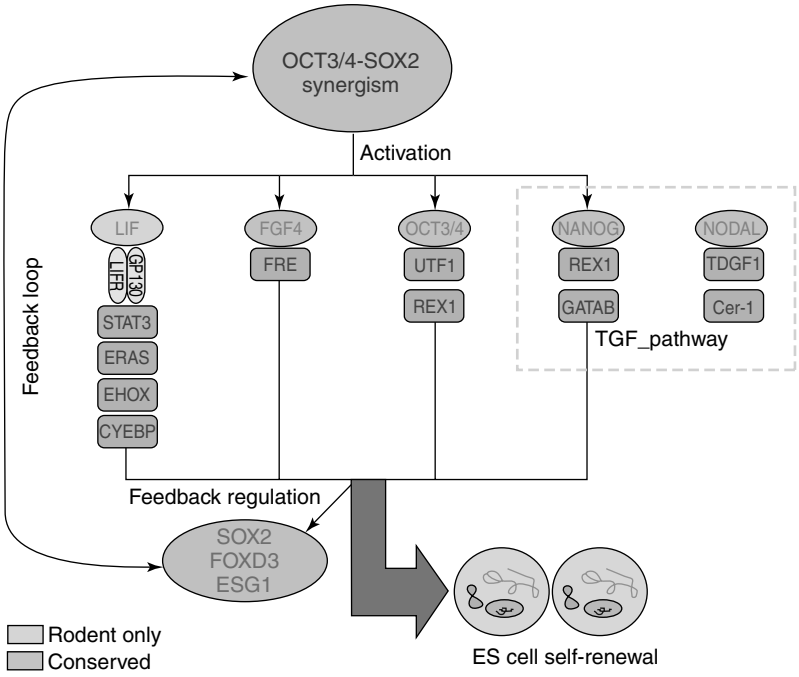

Fig. 4 Pathways to self-renewal in ESC – A model of the multiple pathways whose activation is required to maintain ES cells in an undifferentiated state. Model courtesy Dr M. Zhang (NIA).

differences reported from limited comparisons is quite surprising and may indicate evolutionary pressure for speciation.

5 Differentiation of ES Cells

ES cells can be induced to differentiate by altering culture conditions, injecting them into mice, or developing blastocysts or generating embryoid bodies by a process of aggregation, and many reports have provided evidence of the ability of direct ES cell differentiation toward particular lineages. Some generalizations of the process of differentiation can be made (see Fig. 5).

In no case has it been possible to direct 100% of the cells toward particular phenotype, and, in general, the efficiency of differentiation has been in the 10 to 20% range. Not enough markers (see Fig. 6) have been identified to allow generalized sorting strategies that have

Fig. 6 Markers to define ESC – The table summarizes some of the common markers used to examine ES cell colonies. Note that absence of markers of differentiated cells is an important criterion for determining if ES cells are undifferentiated. Panel on the right shows double labeling with two ES cell markers, while the lower panel shows the results of a PCR (polymerase chain reaction) amplification of ES cell markers in undifferentiated ES cells and differentiated cells. 1 = ES cells, 2 = embryoid body cells.

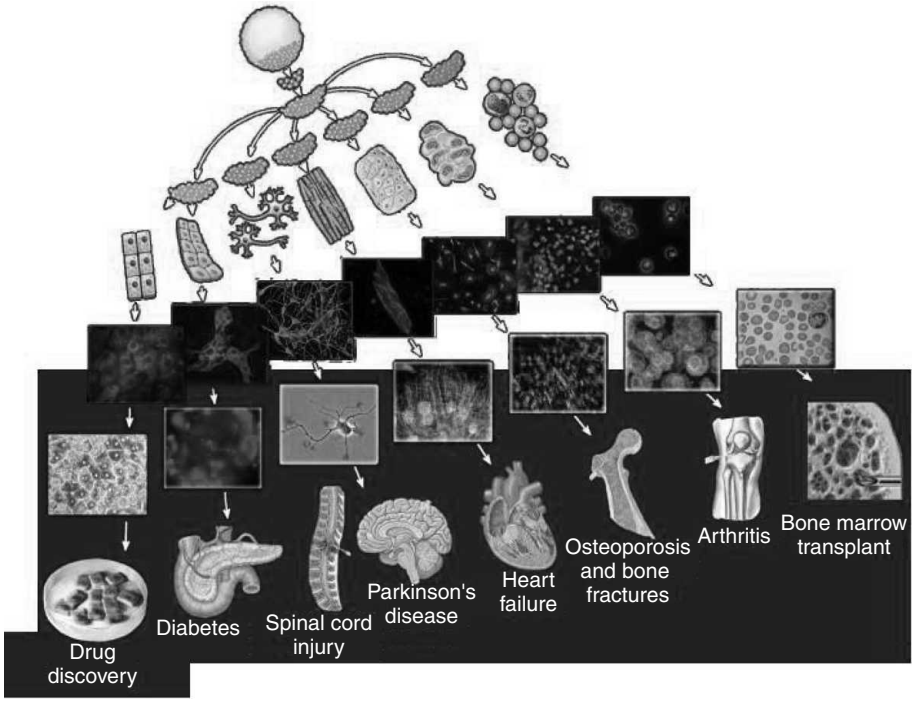

Fig. 5 Differentiation of ES cells – ES cells are capable of differentiating into an astounding variety of cells under the appropriate culture conditions or after transplantation in animal models. The figure summarizes some of the cells types that have been generated from hESC cultures. Figure courtesy Dr J. Lebkowski (Geron).

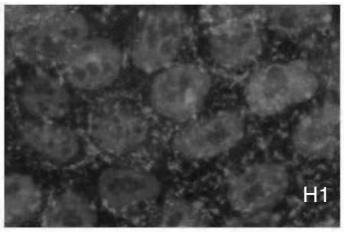
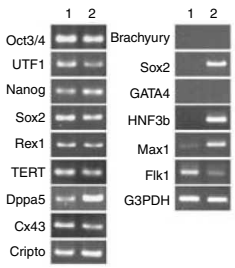
Markers
Alkaline phosphatase SSEA1, SSEA4, TRA160, TRA181/CD9/E-cadherin
Sox, oct, nanog, Rex, utf-1,dppa5
Absence of trophoectoderm markers (BEX)
Absence of neuroectoderm (SOX-1)
Absence of endoderm (GATA genes, HNF3β, PDX-1)
Absence of mesoderm (brachyury, MSX-1)
Cell cycle/TERT/karyotype/gap junctions





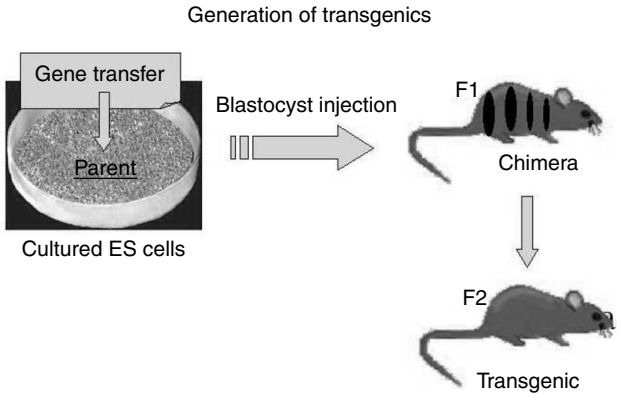


Fig. 7 Generation of transgenics – The figure summarizes the process of making transgenics. This particular use of ES cells has revolutionized the study of early developmental events and has allowed biologists to generate precise models of human disease in mice. The fear that similar strategies may be employed using hESC has raised concerns and much political debate.

been possible in other systems to be used with equal efficiency. In general, tissues or cell types that are generated early in development are easier to produce from ES cell cultures with current technology. Cells that do differentiate generally have fetal or embryonic characteristics, are not identical to adult cells, and, in many cases, are functionally immature. The differentiation process, while more rapid than that seen during embryonic development, is nevertheless slow, and it is unclear as to how much time in culture will be required to obtain differentiated human cells.

Progress in identifying and initiating studies to solve these constraints on the use of ES cell–derived differentiated cells has been rapid, though much remains to be done. Already, preliminary experiments have been performed that show that dopaminergic neurons, which are lost in Parkinsons Disease, can be generated from hESC cultures. Transplant experiments in mouse models have shown functional integration and prolonged survival with modest improvements in behavioral readouts. Similar promising results have been obtained with transplants in a spinal cord injury model and in a cardiac injury model. Pancreatic islet differentiation has been demonstrated from mouse ES cells, and preliminary reports suggest that a similar strategy can be used to generate islet cells from hESC as well (see Fig. 7).

The field is still in its infancy, and much needs to be understood about the process of differentiation. However, the initial results with biasing differentiation, isolating specific types of cells, and transplanting in animal models of disease have shown enough promise that scientists have been encouraged to proceed further.

6 Other Stem Cell Populations, ES-like Cells, Primordial Germ Cell, and Epiblast Cells

As the blastocyst matures, it undergoes a process of gastrulation to generate cells that will contribute to the different germ layers. The trilaminar embryo, formed as

gastrulation proceeds, will undergo additional morphogenetic movements and further progressive differentiation to generate more differentiated cells, tissues, and organs. What has become clear is that the process of differentiation involves the sequential generation of cells, which can still divide and self-renew, and thus fulfill the criteria of stem cells.

These more tissue-specific stem cells have been classified on the basis of their differentiation ability (hepatic, muscle, neural, hematopoietic etc.), and differ from embryonic stem cells (ESCs) by numerous criteria (see above). These tissue-specific stem cells are present throughout development, and may be present in the adult organism as well. Adult tissue-specific stem cells have been harvested from a variety of tissues, including neural and hematopoietic tissue, and adult HSCs are used for a variety of therapeutic purposes.

It is unclear if ICM cells are set aside during development or persist in special niches in the adult. The general consensus has been that they do not. However, two reports have suggested otherwise. Perhaps the most widely studied is the multipotent adult progenitor cell (MAPC) derived from mesenchymal cell cultures and first identified by Catherin Verfaille and colleagues. More recently, Young and colleagues have suggested that pluripotent cells persist as a rare population in multiple tissues (see Fig. 8). These cells that no doubt differ from ICM-derived ES cells by multiple criteria, however, may be functionally equivalent for therapeutic applications and may have the potential advantage of being derived from the individual requiring cell

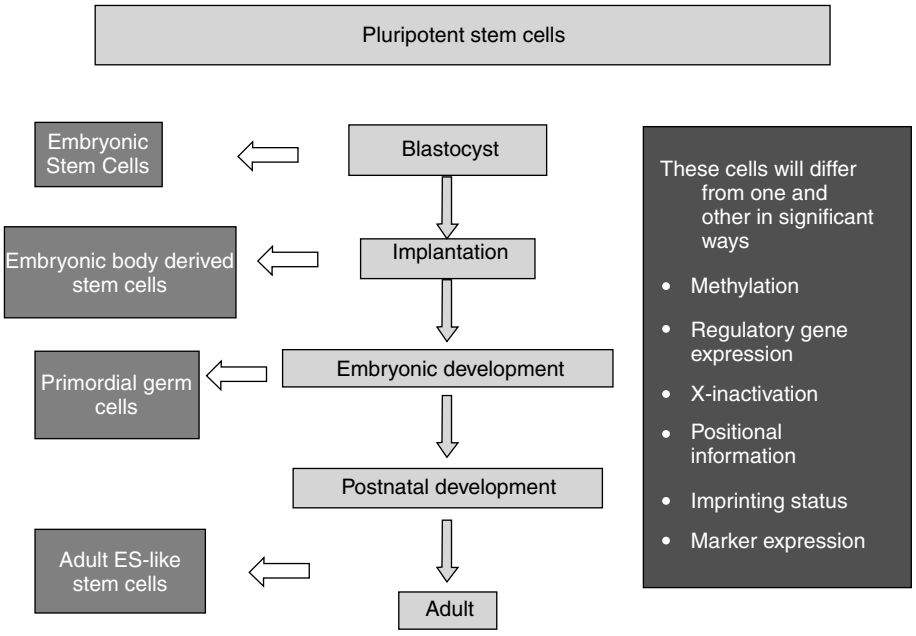

Fig. 8 Pluripotent cells – ES cells as well as cells derived from later stages of embryonic development may be pluripotent and capable of generating ectoderm, endoderm, and mesoderm derivatives. However, these cells will differ from each other in marker expression and other changes that occur as development proceeds.

therapy. In addition to these two populations, other investigators have suggested that stem cells (non-ESC), though tissue specific in their contribution during development, can be induced to reacquire additional capabilities by manipulating cell culture conditions or exposing them to drugs that alter nuclear structure or exposing them to cytoplasm from ES cells, unfertilized eggs, or germ cell tumors. These transdifferentiated or dedifferentiated cells, while differing from ES cells, may be functionally equivalent for therapeutic applications. The possible existence of such cells has fanned an ethical debate on determining whether deriving new ES lines is more appropriate or whether one should focus on dedifferentiating or transdifferentiating adult stem cells. In any case, it has fueled a drive to assess the properties of pluripotent cells and understand the underlying differences between stem cell populations (see Fig. 9).

In addition to ES-like and transdifferentiated cell populations, two additional populations of cells merit mention. These are primordial germ cells that represent the precursor of the sperm and oocyte and epiblast cells, which are present at a stage of development soon after gastrulation. Both of these populations appear similar to ESC in that they are pluripotent, express many of the markers characteristic of ESC including ES cell enriched genes, and

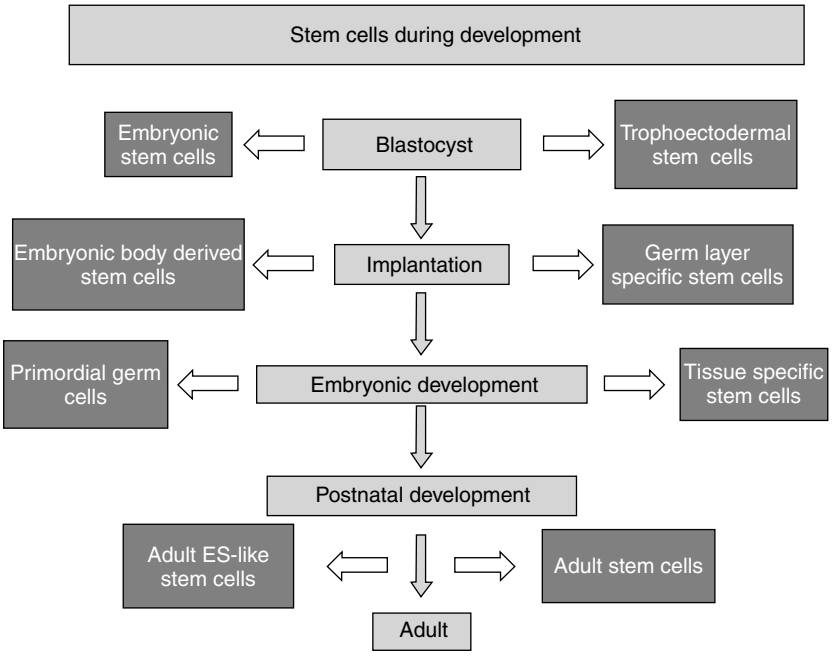

Fig. 9 Adult stem cells. ES cells and other pluripotent cells need to be distinguished from cells derived from more mature stages of embryonic, fetal, or postnatal development. These cells differ from ES cells, but may offer benefits distinct from those of ES cells. It is important to note that adult cells can be derived from ES cell cultures and, as such, the field of regenerative medicine does not consider choices to be either one type of cell or another. Rather, each cell type is uniquely suited for particular therapeutic indications.

can contribute to the germ line after blastocyst injection. These pluripotent stem cell populations do differ from ES cells in patterns of methylation, X chromosome inactivation, growth conditions, and growth factor requirements. However, their functional similarity suggests that these cells may be potential alternates for therapeutic use, more so when compared with transdifferentiated cells or ES-like cells. Work on germ cells and embryoid body derived cells was pioneered by Brigid Hogan and John Gearhart, and these lines offer a valuable alternative to ICM-derived pluripotent ESC lines.

7 Uses of Embryonic Stem Cells

Perhaps the most common use of mouse ES cells has been to generate transgenic mice. In the early 1980s, soon after the successful isolation of ES cell lines, Mario Capecchi and colleagues showed that it was possible to insert foreign DNA into a specific genomic locus via a process termed *homologous recombination*. This has allowed replacement of defective genes with a corrected copy, insertion of reporter molecules to trace the development of cells, or alteration of the levels of a particular product to assess the effect of changing a single protein. This remarkable ability to study directed changes throughout development has offered an unprecedented insight into the biology of complex organisms and has transformed developmental biology.

ES cells, by recapitulating development *in vitro*, have also provided a window into early developmental processes such as X chromosome inactivation, regulation of methylation, segregation of maternal and paternal mitochondria, evolutionary differences, speciation, and the differentiation of germ cells. Somatic nuclear transfer has allowed cloning of mice, sheep, cows, and pigs, and has been widely heralded in the animal husbandry field as a technique to perhaps revive extinct species or develop better strains of animals. These techniques are routinely used and some have been commercialized.

Human ESCs are currently not used in any clinical or commercial application, although there is much excitement about their potential use, and a wide variety of strategies have been proposed. An obvious use of hES cells is to use them as a source of cells for transplantation, and indeed much of the current focus is on isolating cells of the appropriate phenotype for cell replacement. Isolation and transplantation of dopaminergic neurons to treat Parkinson's disease, islet cells to treat diabetes, and cardiac muscle to treat heart failure are strategies under evaluation.

Many other uses of hESCs can be envisaged. These include modifying transplant strategies to take advantage of the unique properties of hESC behavior *in vivo*, using hESC in gene and drug discovery strategies, and using hESC to understand the basic biology of early developmental events such as mitochondrial segregation, regulation of telomerase expression, or maintenance of the pluripotent state. These additional or alternate uses of hESC do not require any fundamental breakthroughs; rather, these are an adaptation of the existing technology to hESC cultures. These specific and unique uses of hESC represent an important and less-discussed aspect of the advantages of hES cells over other cell types.

Additional techniques and manipulation strategies have provoked controversy even while promising possible novel therapies.

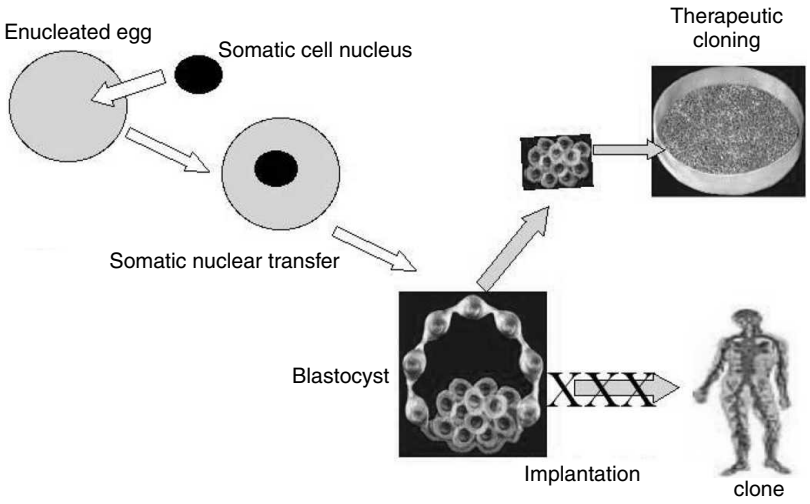

Fig. 10 Therapeutic cloning – The process of enucleating a fertilized egg and replacing it with a nucleus from any cell is termed *nuclear transfer* and such a compound egg can be implanted and, in a small number of cases, can lead to the development of viable offspring. Such cloned offspring are genetically identical to the donor nucleus, and the process of cloning is in use in animal husbandry. In humans, compound eggs can be used to generate ES cell lines that are genetically identical to the donor. These lines could then be used as a source for immunologically matched cells.

The ability to transfer a nucleus from any cell in the body to a fertilized egg that has been enucleated to generate novel ES cell lines (therapeutic cloning) or an embryo that can survive to term (cloning) in animals has raised fears that this theoretical possibility may be actualized in humans as well. The ability to generate ES lines from embryos that carry a genetic defect diagnosed at the time of blastocyst implantation by PGD (preimplantation genetic diagnosis) has important potential benefits in understanding the etiology and progression of congenital diseases. Nevertheless, enthusiasm has been tempered by concerns that embryos may be specifically created to generate designer ES cell lines (see Fig. 10).

The rich and unique promise of ES cell biology coupled with real and perceived risks of misuse of this promise has provoked healthy debate, has raised fears of disruptive social change, and guarantees interesting times ahead.
